Kelley, University of Washington and the Lost City Team.

obligate need (aerobes) while others cannot tolerate O_2 at all (anaerobes). Furthermore, some organisms require low levels of O_2 (microaerophile) while others can switch between aerobic and anaerobic metabolisms (facultative anaerobe).

At deep-sea vents, the heat and pH preference provides an additional habitat selection. All microbes have a preferred temperature range at which optimal growth is achieved. Psychrophiles have optimal growth $\leq 15^\circ\text{C}$, mesophiles grow optimally between 25 and 40°C , thermophiles and hyperthermophiles grow optimally between 45 and 80°C , and $\geq 80^\circ\text{C}$, respectively.

The pH gradients at deep-sea vents can vary from as low as pH 2.5 to over pH 8.0, as the acidic hydrothermal fluid mixes with the cold seawater. Thus, there are habitats of low pH where acidophiles thrive; however, by far the majority of habitats at vents available for microbial colonization are circumneutral (pH $>6 <8$), and these organisms are therefore referred to as neutrophiles.

Energy sources

Seafloor hydrothermal ecosystems are supported almost entirely by chemosynthetic primary production fueled by the chemical disequilibrium between the oxygenated seawater and the reduced hydrothermal fluids. Microorganisms capture this energy by way of reduction/oxidation (redox) reactions in which seawater typically provides the oxidant (O_2 , SO_4^{2-} , NO_3^- , CO_2) and the hydrothermal fluids provide the reductant (H_2 , H_2S , HS^- , S^0 ,

$S_2O_2^{3-}$, Fe^{2+}). Redox reactions generate energy that is used to fix CO_2 into cellular material which then provides organic carbon for various heterotrophic microbes and animals that make up the rest of the community. Some of the most thermodynamically favorable reactions found in marine hydrothermal environments are presented in Table 2. Reactions are expressed in terms of the change in free energy (ΔG), where the more negative the value the more energy an organism will gain by catalyzing the reaction. Calculated values suggest that aerobic oxidation of reduced sulfur compounds (HS^- , S^0 , $S_2O_2^{3-}$) are the most energetically favorable and potentially the most significant reactions in terms of biomass production in marine hydrothermal environments. It is important to note, however, that thermodynamic calculations can be misleading as they do not consider the bioavailability of certain reactants and potential kinetic inhibition under different environmental conditions (Takai et al., 2006). Several past studies have attempted to model the overall energetics in a variety of marine hydrothermal systems considering such factors (McCollom and Shock, 1997; McCollom, 2000; McCollom, 2007). An interesting conclusion from a theoretical study is that four times as much energy per kg of hydrothermal fluid is available to H_2 oxidizers in ultramafic hosted systems than to sulfur oxidizers because of the increased concentrations of H_2 (McCollom, 2007). This suggests that H_2 oxidizers may be more important than sulfur oxidizers in ultramafic hosted systems (McCollom, 2007). A recent report lends support to

Hydrothermal Environments, Marine, Table 2 Examples of thermodynamically favorable redox reactions utilized by microorganisms from marine hydrothermal environments

Conditions	Electron donor	Electron acceptor	Free energy ΔG^a (kJ/mol)	Metabolic process
Aerobic	H ₂	O ₂	−237	Hydrogen oxidation
	HS [−]	O ₂	−797	Sulfide oxidation
	S ⁰	O ₂	−585	Sulfur oxidation
	S ₂ O ₂ ^{3−}	O ₂	−952	Thiosulfate oxidation
	Fe ²⁺	O ₂	−44.3	Iron oxidation
	NH ₄ ⁺	O ₂	−275	Nitrification
	CH ₄ + other C-1 compounds	O ₂	−810	Methane oxidation
	Organics	O ₂	−477	Heterotrophic metabolism
	Organics	O ₂	−477	Heterotrophic metabolism
Anaerobic	H ₂	NO ₃ [−]	−239	Denitrification
	H ₂	S ⁰	−98.3	Sulfur reduction
	H ₂	SO ₄ ^{2−}	−38.1	Sulfate reduction
	H ₂	CO ₂ ^{2−}	−34.7	Methanogenesis
	Organics	SO ₄ ^{2−}	−40.6	Heterotrophic sulfate reduction

this hypothesis, as the diversity of H₂-oxidizing bacteria was found to increase as the concentration of H₂ gas increased in vents sampled from the ultramafic hosted Logatchev vent field along the MAR (Perner et al., 2007). These studies speak to the tight coupling of geochemistry and microbial primary production in marine hydrothermal environments.

Microbial habitats and diversity

Seafloor hydrothermal systems provide several habitats over a wide range of physical environments that sustain distinct microbial communities. Such environments include active and inactive vent structures, biotic and abiotic surfaces receiving hydrothermal fluid inputs, inside vent animals (endosymbionts), and hydrothermal vent plumes (Figure 2) (reviewed in Karl, 1995a; Van Dover, 2000; Kelley et al., 2002; Takai et al., 2006). Many of these environments are exposed to varying inputs of hydrothermal fluids, resulting in fluctuating temperatures and chemistry. Below is a brief discussion of each of these habitats and their associated microbial biodiversity. These biodiversity assessments are based on growing and characterizing isolates under laboratory conditions (culturing techniques) and through molecular phylogenetic approaches that are culture-independent. This latter approach is based on extracting genomic DNA from environmental samples, and then amplifying a diagnostic phylogenetic marker for Bacteria and Archaea, the small subunit rRNA gene (16S rRNA), using the polymerase chain reaction.

Active sulfide structures

Using culture-dependent and culture-independent techniques, a rich diversity of Bacteria and Archaea have been found associated with active sulfide structures (reviewed

in Jannasch, 1995; Karl, 1995b; Kelley et al., 2002; Takai et al., 2006). Free-living microorganisms supported by active sulfide structures include mesophilic, thermophilic, and hyperthermophilic chemolithoautotrophs, heterotrophs, and mixotrophs. Organisms can be anaerobes, facultative anaerobes, microaerophiles, and obligate aerobes.

In general, Bacteria are the most numerically abundant microorganisms associated with active sulfide structures (reviewed in Jannasch, 1995; Karl, 1995b; Kelley et al., 2002; Takai et al., 2006). Their abundance can range anywhere from 35 to 99% of the microbial population, depending on the method used to measure abundance, the type of vent feature, and where within a chimney structure one examines (Harmsen et al., 1997; Takai and Horikoshi, 1999; Takai et al., 2001; Hoek et al., 2003; Schrenk et al., 2003; Nakagawa et al., 2006).

Within the Bacteria, members of the epsilon-Proteobacteria have consistently been found to dominate microbial communities in deep-sea hydrothermal environments (Reysenbach et al., 2000; Campbell et al., 2001; Hoek et al., 2003; Nakagawa et al., 2005). These free-living deep-sea epsilon-Proteobacteria are mesophilic to moderately thermophilic. Recently, several representatives have been obtained in pure culture that are chemolithoautotrophs capable of oxidizing H₂ and sulfur compounds while using O₂, NO₃[−], or sulfur compounds as terminal electron acceptors (reviewed in Campbell et al., 2006). Like in cave environments, the epsilon-Proteobacteria play an essential role in sulfur cycle at deep-sea vents.

Other commonly identified but less abundant bacterial members of the free-living microbial communities include the thermophilic *Aquificales* and *Thermotogales* (reviewed in Miroshnichenko and Bonch-Osmolovskaya, 2006). The *Aquificales* are globally distributed in marine

hydrothermal environments but are restricted to active sulfide structures and hydrothermal fluids due to their thermophilic lifestyle. They are generally chemolithoautotrophs and chemoorganotrophs capable of oxidizing H_2 , S^0 , and $S_2O_3^{2-}$ either aerobically or anaerobically (NO_3^- or sulfur compounds) (Reysenbach, 2001a). The *Thermotogales*, on the other hand, are strictly anaerobic, thermophilic heterotrophic fermenters (Reysenbach, 2001b).

As stated above, Archaea are less abundant in active sulfide structures, yet they play a key biogeochemical role especially at the higher temperatures. Some of the most exhaustive studies on microbial diversity at deep-sea vents have focused solely on the Archaea revealing a high phylogenetic and metabolic diversity within this domain (Takai and Horikoshi, 1999; Takai et al., 2001; Nercissian et al., 2003; McCliment et al., 2006). Most of the Archaea found here are thermophilic to hyperthermophilic and are thus restricted to areas most influenced by hydrothermal fluids. Within the Archaea, the two main phyla, the Crenarchaeota and Euryarchaeota, are well represented, while the enigmatic "Korarchaeota" and "Nanoarchaeota" are rarely detected (reviewed in Takai et al., 2006).

Crenarchaeota commonly detected at active sulfide structures include cultivated members of the Desulfurococcales (e.g., *Pyrodictium* and *Pyrolobus*) and several uncultivated groups such as the deep-sea hydrothermal vent crenarchaeotic group (DHVC1), and the marine group I (Takai and Horikoshi, 1999; Takai et al., 2006). *Pyrodictium* is an example of a hyperthermophilic mixotrophic organism with the ability to use either H_2 or complex organics to reduce elemental sulfur (reviewed in Reysenbach et al., 2002). *Pyrolobus* is also a hyperthermophile but, unlike *Pyrodictium*, *Pyrolobus* is an obligate chemolithoautotroph that can only use H_2 to reduce nitrate (NO_3^-), thiosulfate, ($S_2O_3^{2-}$) or O_2 .

Euryarchaeota commonly found at marine hydrothermal systems include the hyperthermophilic methanogens (*Methanocaldococcus* spp.), the hyperthermophilic SO_4^{2-} reducing *Archaeoglobales*, and a variety of thermophilic fermentative *Thermococcus* species (Takai and Horikoshi, 1999; Takai et al., 2006). While these are readily grown in the laboratory, their relative abundance in the environment has been shown to vary from one site to another (Reysenbach et al., 2000; Takai et al., 2001; Hoek et al., 2003; Nercissian et al., 2003; McCliment et al., 2006). Several lineages often detected at vent sites around the globe have been classified as the Deep-sea Hydrothermal Vent Euryarchaeotal Groups (DHVEG) (Takai and Horikoshi, 1999; Reysenbach et al., 2000; Takai et al., 2001; Hoek et al., 2003; Nercissian et al., 2003). Several subdivisions exist within this group but at least one lineage, the DHVEG-2, appears to be endemic to deep-sea vents. Little was known about this lineage until Moussard et al. (2006) showed optimal activity and thermostability of a DNA polymerase belonging to this lineage which suggested a thermophilic lifestyle. Thermophily was confirmed when the first isolate

was obtained in pure culture (Reysenbach et al., 2006). The organism, *Aciduliprofundum boonei*, is a heterotrophic thermoacidophile capable of fermenting peptides and reducing Fe and S. Isolation of this organism was significant because it is the first obligate acidophile isolated from a deep-sea vent and the first member of the DHVEG-2 lineage to be grown. Prior to this discovery, the absence of acidophiles from a deep-sea vent had always puzzled microbiologists as hydrothermal fluids are acidic, and geochemists had predicted the presence of acidic microhabitats within sulfide chimneys (Von Damm, 1995; Tivey, 2004).

Inactive sulfide structures

Hydrothermal fluid flow through individual sulfide structures is temporary as subsurface flow paths constantly change and chimneys collapse. Inactive sulfides are subjected to low-temperature oxidative weathering in which the reduced sulfur moiety is converted to soluble SO_4^{2-} and the metals, mostly Fe, are converted to insoluble oxyhydroxide crusts (Juniper and Tebo, 1995). Oxidation occurs abiotically as oxygenated seawater penetrates the rock, but can also be mediated by S- and Fe-oxidizing bacteria (reviewed in Edwards, 2004; Edwards et al., 2005). While microbial mediated sulfide weathering in terrestrial systems has been studied for decades, this area of research is in its infancy in the deep sea (Edwards et al., 2003a, b; Edwards, 2004; Rogers et al., 2003; Suzuki et al., 2004). Culturing studies have resulted in the isolation of several psychrophilic, neutrophilic Fe-oxidizing bacteria belonging to the alpha- and gamma-divisions of the Proteobacteria from sulfide rocks collected along the Juan de Fuca Ridge (Edwards et al., 2003a). A follow-up study with one of the gamma-Proteobacteria isolates showed that the organism promoted the dissolution of native sulfide minerals under anaerobic conditions (Edwards, 2004). Although the mechanism of dissolution remains unclear, these studies illustrate that Fe-oxidizing bacteria are associated with extinct sulfide minerals on the seafloor and can actively promote the dissolution of these minerals at least in the laboratory.

Carbonate structures of Lost City

Microbial communities found in active carbonate structures at the Lost City vent field differ from those found in active sulfide structures due to the contrasting physical and geochemical conditions. Inner portions of carbonate chimneys in contact with hydrothermal fluids tend to be covered by thick microbial biofilms dominated by a single Archaeal phylotype belonging to the Methanosarcinales (Schrenk et al., 2004; Brazelton et al., 2006). The Methanosarcinales are the most metabolically diverse of all the methanogens, with various representatives known to generate CH_4 from acetate and H_2/CO_2 or by dismuting methyl compounds (Boone et al., 2001). Members of the Methanosarcinales also participate in a nonobligatory syntrophic relationship

with SO_4^{2-} reducing bacteria that results in the anaerobic oxidation of methane (AOM) in oceanic cold seep environments (Orphan et al., 2001). A second archaeal phylotype belonging to the closely related ANME-1 was identified in weakly flowing and extinct carbonate chimneys (Brazelton et al., 2006). Like the Methanosarcinales, the ANME-1 are involved in AOM but appear to mediate this process without a SO_4^{2-} reducing partner and at lower temperatures (Orphan et al., 2002). As the Methanosarcinales and the ANME-1 found at Lost City were only identified by molecular techniques, it is difficult to speculate on whether they are producers or consumers of CH_4 .

In contrast to the Archaea, Bacteria appear to be more diverse in active and inactive carbonate chimneys (Brazelton, et al., 2006). The most diverse bacterial group at Lost City is the gamma-Proteobacteria which includes close relatives of known chemolithoautotrophic S- and HS^- -oxidizers (e.g., *Thiomicrospira* spp.) and several methylophilic (CH_4 -oxidizing) genera (e.g., *Methylobacter*, *Methylomonas* and *Methylophaga*). Other chemolithoautotrophic S-oxidizing bacteria belonging to the epsilon-Proteobacteria are also found at Lost City.

Perhaps the most interesting trend in bacterial diversity observed at Lost City is not what is present but what has not yet been detected. Specifically, neither any known thermophilic H_2 -oxidizing Bacteria (i.e., *Aquificales*; common in most deep-sea and terrestrial hot spring environments) nor members of the delta-Proteobacteria (the SO_4^{2-} -reducing syntrophs found in other AOM environments), were identified in carbonate chimneys (Brazelton et al., 2006). The lack of bacterial H_2 oxidizers is unexpected as geochemical modeling suggests that H_2 oxidation provides four times as much energy per kg of hydrothermal fluid than S oxidation in ultramafic hosted systems (McCollom, 2007). This suggests that available energy may not be the main constraint driving which microbial metabolisms can be supported in particular environments. It is important to note, however, that relatively few studies have been conducted at Lost City and that these observed trends may be due to the lack of adequate sampling or incorrect inferences based solely on 16S rRNA gene similarity.

Biotic and abiotic surfaces

Microbes are opportunistic organisms and will colonize any surface where growth substrates are provided. In areas influenced by hydrothermal fluids, this includes the sulfide deposits as described above and surfaces of invertebrate animals (reviewed in Van Dover, 2000). Some of these relationships are commensal as the host does not appear to gain an advantage by being colonized while others truly are symbiotic (episymbiosis), with both the host and microbes benefiting. An example of a commensal relationship is found between the giant tube worm *Riftia pachyptila* and the diverse microbial communities that colonize the outside surfaces of its chitinous

tube (López-García et al., 2002). Most of the microbes identified on the outside of the tube are members of the ubiquitous epsilon-Proteobacteria and are likely oxidizing the reduced sulfur compounds in the hydrothermal fluids. An episymbiotic relationship is found on the polychaete worm *Alvinella pompejana* (Van Dover, 2000). *Alvinella pompejana* lives in tubes on the sides of black smoker chimneys where water temperatures can exceed 70°C (reviewed in Desbruyeres et al., 1998). It has a fully functional digestive system and appears to feed upon microbial mats inside of its tube as well on sulfide surfaces. The worm also houses diverse microbial communities on its dorsal surfaces including microaerophilic H_2S -oxidizing members of the epsilon-Proteobacteria. Although the exact nature of this relationship is unknown, it is thought that the bacteria may detoxify H_2S or provide nutritional supplement to the worm.

In addition to surfaces of vent animals, microbes often colonize rocks and sediments surrounding hydrothermal vents. These environments are primarily sustained by hydrothermal fluids flowing diffusely through the underlying porous sediments. The most well-studied and possibly most diverse microbial mat system found in marine hydrothermal environments is in the sediment-hosted Guaymas Basin. Microbes found here include thermophilic/mesophilic methanogens and methanotrophs (Dhillon et al., 2005), SO_4^{2-} reducing Bacteria (Kallmeyer and Boetius, 2004), H_2S -oxidizing gamma-Proteobacteria (Nelson et al., 1989), and even spore forming Mn-oxidizers (Dick et al., 2006). Much of this diversity is fueled by the presence of overlying sediments which provides different combinations of organic/inorganic substrates typically not found in non-sediment-hosted systems.

Endosymbionts

Several invertebrate animals form obligate symbiotic relationships in which the bacteria are hosted inside the animal cells. The most well-studied example is in the giant tube worm *Riftia pachyptila* (reviewed in Minic and Hervé, 2004). As adults, *Riftia* completely lack a mouth, the digestive system and anus and are sustained by chemoautotrophic H_2S -oxidizing Bacteria belonging to the gamma-Proteobacteria (Cavanaugh et al., 1981; Felbeck, 1981; Jones, 1981; Minic and Hervé, 2004). In this relationship, *Riftia* provide the bacteria with inorganic carbon, O_2 , H_2S , and NO_3^- and, in turn are provided with organic carbon. Other invertebrate organisms such as the giant clam *Calypotgena magnifica* and the mytilid mussels *Bathymodiolus* spp. also house H_2S -oxidizing endosymbionts in their gill tissues (Van Dover, 2000). The symbiotic relationship between mussels and bacteria, however, is not obligate as they retain some of their filter feeding capabilities. In addition, certain species of *Bathymodiolus* have methanotrophic (CH_4 -oxidizing) endosymbionts and even dual symbionts with both sulfur- and CH_4 -oxidizing bacteria.

Hydrothermal plumes

Upon reaching neutral buoyancy, hydrothermal vent plumes carrying elevated concentrations of S, metals (Fe and Mn), H₂, and CH₄ extend hundreds of meters laterally into the water column. Not surprising, elevated biomass has been detected in plumes, suggesting that these environments are areas of high productivity (reviewed in Winn et al., 1995). Methane oxidation has been measured in plume waters collected along the Juan de Fuca Ridge, further supporting microbial activity in vent plumes (DeAngelis et al., 1993). More recently, Sunamura et al. (2004) used culture-independent techniques to assess the diversity of microbes in plumes over the Suiyo Seamount. Members of the gamma- and epsilon-Proteobacteria were dominant in the plume waters and are likely using reduced sulfur compounds because of their close phylogenetic relationship with known sulfur-oxidizers (Sunamura et al., 2004).

The first aerobic anoxygenic photosynthetic bacteria from the deep sea were isolated from plumes (Yurkov and Beatty, 1998). These organisms belong to the alpha-Proteobacteria and appear to supplement heterotrophic growth with photosynthesis under laboratory conditions. Their presence in deep-sea hydrothermal environments seems puzzling because of the lack of sunlight, but high-temperature fluids ($\approx 350^{\circ}\text{C}$) have been detected to emit photons capable of supporting facultative photosynthetic bacteria (Van Dover et al., 1996). Their role and significance in the environment, however, remain unknown.

Conclusions

Although we know significantly more about the diversity of microorganisms from deep-sea vents since their discovery in the late 1970s, we still have a rudimentary understanding of their ecology and geobiology. Recently, the discovery of acidophiles (Reysenbach et al., 2006), high-temperature nitrogen fixation (Mehta and Baross, 2006), and high-temperature Fe reduction (Kashefi and Lovley, 2003) provided additional insights into the roles microbes play in biogeochemical cycling at vents. Furthermore, studies are now being undertaken to explore the temporal changes that occur in the microbial communities as the available carbon and energy sources change (e.g., Pagé et al., 2008). Whether these changes are due to the in situ biological activity or due to the geochemical constraints of the hydrothermal fluids and mixing and subsurface reaction zones is still unknown. It is clear that deep-sea vents represent one of the few places on Earth where the “bio” is so tightly coupled to the “geo.”

Definition

Hydrothermal Environments, Terrestrial. Areas on the Earth's surface that are under the influence of geothermal waters, steam, and associated gases discharged from hot springs, geysers, and fumaroles.

Introduction

Terrestrial hydrothermal environments are those settings where fluids discharge either at or close to the land surface at a temperature that is significantly above the local ambient air temperature. The hydrothermal processes transfer heat and dissolved matter to the surface in a liquid or vapor (gas) phase. Those fluids originate at variable depths below the Earth's surface and have a wide range of temperature and chemical composition. Visible features of terrestrial hydrothermal environments include hot springs, geysers, fumaroles, and steam vents. Travertine (calcite and aragonite: CaCO_3) and sinter (mainly opal-A: $\text{SiO}_2 \cdot n\text{H}_2\text{O}$), precipitated from thermal water, commonly form mounds and terraces around many spring and geyser vents. In contrast, chemical reactions between acidic hydrothermal fluids and the host bedrock and soils usually produce extensive hydrothermal alteration that generates a very different type of landscape.

Since the pioneering studies of life in hydrothermal environments, begun in the 1960s by Brock (1978) and colleagues, interest in these environments has increased significantly for many reasons (Bock and Goode, 1996; Renaut and Jones, 2000; Jones and Renaut, 2003a). The extremophiles that inhabit modern high-temperature settings, which include thermophiles and thermoacidophiles, have implications for understanding the origin of life on the Earth and potentially on other planets. Many of the rocks precipitated around hot springs have stromatolitic fabrics and contain numerous fossilized microbes. Many recent studies have tried to determine if such microbes

directly influence mineral precipitation, or are simply trapped in essentially abiotic mineral deposits. From a geological perspective, surface hydrothermal environments can provide clues to subsurface processes including the potential for epithermal ore mineralization and for geothermal energy development (Pirajno, 1992; Bogie et al., 2005).

Geothermal fields

The geothermal gradient, a measure of the increase in temperature with depth in the Earth's crust, has an average value of $25\text{--}30^\circ\text{C km}^{-1}$, but this may rise to several hundred $^\circ\text{C km}^{-1}$ in regions of volcanic activity. Geothermal systems are found in regions with normal and slightly elevated geothermal gradients, but high-temperature systems are most common in regions of active tectonics and volcanism near plate margins (Figure 1). Although geothermal fields can extend over several thousand square kilometers, the individual surface areas of hydrothermal discharge tend to be localized and of limited extent within those domains.

Using stable isotopic evidence, Craig (1963) confirmed that most hydrothermal fluids are meteoric in origin. Some hydrothermal systems are partly fed by connate (formation) waters that were buried along with the host sediments; other hydrothermal fluids may derive from juvenile (magmatic) and metamorphic waters, but these are usually minor components if present (Nicholson, 1993; Giggenbach, 1994).

The fluids that feed high-temperature (high-enthalpy) liquid-dominated hydrothermal systems derive mainly from cool meteoric water that has circulated to a few kilometers depth (up to ~ 5 km) via faults, fractures, and permeable horizons. The heated fluids react with host rocks, acquire solutes, and typically evolve to become saline ($3,000\text{--}5,000 \text{ mg kg}^{-1}$) and chloride-rich, forming geothermal reservoirs with temperatures of up to $\sim 400^\circ\text{C}$. Those fluids then rise convectively and may boil with the decreasing pressure during ascent to create a two-phase (steam + liquid) zone below the land surface. The liquid phase may discharge at the surface as hot springs, whereas the vapors released on boiling (steam separation) may discharge at the surface as fumaroles. Rising hot fluids may mix with shallow groundwaters before surface discharge, which may modify their composition and temperature. Not all geothermal systems are of high-temperature type. In low-temperature (low-enthalpy) systems, the reservoir temperature may be $<150^\circ\text{C}$, and the fluids may not boil before being discharged as springs.

Thermal fluids

Geothermal fluids are commonly classified according to their dominant anion, into chloride waters, sulfate waters, and bicarbonate waters (Table 1) (Henley and Ellis, 1983; Nicholson, 1993). Waters of mixed anion composition are also found. The composition of the discharged fluids

profoundly affects the characteristics of the terrestrial surface environment, including any mineral deposits and hydrothermal alteration, and the biota that inhabit the areas of hydrothermal discharge.

Chloride waters (also termed “alkali-chloride” or “neutral chloride” waters)

These saline waters typify the deep geothermal fluids in most high-temperature geothermal systems and where discharged at the surface, they commonly overlie permeable zones of major thermal upflow (Nicholson, 1993).

They have near neutral pH and are chloride-rich with variable SO₄²⁻ and HCO₃⁻ concentrations. Chloride waters are typically rich in dissolved silica and have Na⁺ and K⁺ as the dominant cations. Carbon dioxide is usually the main dissolved gas with much lower amounts of H₂S.

At the land surface, chloride fluids commonly discharge from hot and boiling springs, often with clear bluish-green waters, and from most geysers (Figure 2a). Such fluids characteristically precipitate large quantities of silica sinter (see Chapter Sinter). If the fluids are rich in HCO₃⁻, they may boil at greater depths and may

precipitate both sinter and travertine upon CO_2 degassing at the land surface.

Spectacular examples of geysers and springs that eject chloride waters are found in most of the major geothermal sites, including those in Yellowstone National Park (Bryan, 2008), the Taupo Volcanic Zone of North Island, New Zealand (Ellis and Mahon, 1977; Jones and Renaut, 2003b), El Tatio in northern Chile (Cusicanqui et al., 1976; Fernandez-Turiel et al., 2005), and Iceland (Torfason, 1985). The sinter that precipitates around many geyser and spring vents and on their discharge aprons as mounds and terraces is commonly colonized by diverse, varicolored, microbial communities.

Sulfate waters ("acid sulfate waters")

Sulfate-rich waters form through condensation of geothermal gases in shallow oxygenated groundwater. Steam, gases, and other volatiles (e.g., NH_3 , As, B) that were originally dissolved in deep geothermal fluids can separate from chloride waters when they undergo boiling at depth, and rise toward the surface. The steam-heated acidic waters commonly boil at the water table because the separated steam contains high enthalpy from the deeper geothermal fluid.

Sulfate, the dominant anion, is formed by oxidation of condensed hydrogen sulfide (Nicholson, 1993):

The protons produced may be supplemented by condensation of CO_2 to create acidic waters:

The pH is typically between 2.8 and ~ 5 . Chloride is usually present in minor amounts. Bicarbonate is usually absent because it is lost from solution as CO_2 gas. These acidic fluids, typically present above the water table close to the land surface (<100 m depth), are usually found around the margins of geothermal fields at sites distant (few hundred meters to several kilometers) from the main chloride-rich upflow.

Acidic waters form distinctive surface environments characterized by hot springs, turbid boiling mud pools, or steaming ground commonly with extensive pits and collapse features resulting from hydrothermal alteration (Figure 2b). The acidic waters leach the host rocks

Hydrothermal Environments, Terrestrial, Figure 2 Variations in modern hydrothermal environments according to water chemistry. (a) Hot springs, geysers, and extensive silica sinter coating a fault scarp at Orakeikorako, New Zealand. The fluids are alkaline chloride waters. (b) Muddy hot springs and fumaroles at Myvatn, northern Iceland. The fluids are acid sulfate in composition. Hydrothermal alteration of young volcanic rocks has produced extensive clays and Fe oxides at the land surface. (c) Boiling hot spring and perpetually spouting hot spring (*right*) rimmed by calcite travertine on the shoreline of Lake Bogoria, Kenya. The spring water is of sodium bicarbonate composition. (d) Small geyser discharging mixed acid chloride-sulfate waters (pH: 2.1–2.6) near Hakereteke Stream, north Waiotapu, New Zealand. Thin Fe-rich sinter covers the substrate.

producing extensive clays (mainly kaolinite), commonly with alunite, alunogen, jarosite, Fe-oxyhydroxides, pyrite, cristobalite, and native sulfur. Little sinter forms in acidic waters, but alteration of volcanic rocks by sulfuric acid can leave behind abundant opaline silica in place, termed “silica residue” (Rodgers et al., 2002). Well-developed examples of acid sulfate water discharge are found at Tikitere (New Zealand), Myvatn (northern Iceland), and Norris Geyser Basin (Yellowstone National Park).

Bicarbonate waters

Bicarbonate-rich hot waters are formed mainly when steam and gases (mainly CO_2) condense in shallow groundwaters. Although most common around the margins of geothermal fields, they may also form in sites distant from volcanic activity. They often form where geothermal fluids are in contact with limestone or volcanic bedrock. Such fluids normally have a near-neutral pH when discharged. The initial acidity of the rising CO_2 -rich fluids is neutralized by hydrolysis reactions with bedrock that consume protons (H^+) leaving waters dominated by HCO_3^- and Na^+ . Sulfate and chloride have variable concentrations. At the land surface, these fluids discharge from springs that range from warm to boiling and most have clear water. Travertine deposits, composed of calcite and (or) aragonite, commonly form around the vent and downslope of these springs (Figure 2c) where sufficient Ca^{2+} is available. Sinter is generally absent, but minor amounts can form from very hot and boiling bicarbonate waters. Hydrothermal alteration at the surface is generally very minor, though more extensive at depth.

Carbonate deposits associated with such springs may be localized around their vents or form vast discharge aprons. Examples include the large terrace mounds, fissure ridges, and related features at Pamukkale in Turkey, Mammoth Hot Springs in Wyoming, and at many sites in central Italy (Bargar, 1978; Chafetz and Folk, 1984; Pentecost, 2005). The travertines precipitate from bicarbonate waters over a wide temperature range, from ambient to boiling. Most carbonate precipitation has been attributed to rapid loss of CO_2 upon discharge of the spring waters at the land surface (Renaut and Jones, 1997; Pentecost, 2005). Microorganisms, principally cyanobacteria, may play a role in some carbonate precipitation through photosynthetic removal of CO_2 , but at high temperatures most precipitation is probably driven by abiotic degassing of carbon dioxide.

Mixed waters

Waters that contain two anions with similar concentrations form by several different processes. *Sulfate-chloride waters* typically have a pH of ~ 2 –5, but can have a pH as low as 0. They originate through subsurface mixing of sulfate and chloride waters, oxidation of H_2S in chloride waters, near-surface condensation of volcanic gases in meteoric waters, or dissolution of sulfate-bearing bedrock by migrating thermal chloride waters (Nicholson, 1993).

Such waters discharge as warm to hot springs, commonly with thin sinter deposits and sulfate-bearing minerals around the vent. Native sulfur may also be present.

Examples of acidic sulfate-chloride springs are found in the northern part of the Waiotapu geothermal area of North Island, New Zealand (Figure 2d) (Jones and Renaut, 2006). These springs discharge waters a pH of 2.1–2.6 at temperatures $>90^\circ\text{C}$. Spicular sinters containing silicified microbes have precipitated around these springs together with kaolinite, jarosite, and gypsum.

Dilute *chloride-bicarbonate* waters form where chloride waters have been diluted by groundwater or bicarbonate water (Nicholson, 1993). They typically are found in springs of variable temperature around the margins of thermal upflow zones, but waters of this composition also discharge in low-temperature systems. The fluids are typically Cl-dominated, have variable HCO_3^- concentrations, and a neutral pH of 6–8. Minor travertine and (or) sinter may form around the vents, but many of these springs lack surface deposits.

Types of geothermal systems

The environmental characteristics of terrestrial hydrothermal sites are strongly controlled by the type of geothermal system that supplies their fluids. Many classifications of geothermal systems have been proposed (e.g., Heiken, 1982; Henley and Ellis, 1983; Pirajno, 1992; Nicholson, 1993). Kühn (2004) recognized two major groups. In *static systems*, heat may be transferred to the surface by conduction without convective fluid movement. In *dynamic systems*, heat is transferred to the surface by moving fluids undergoing convective circulation.

Static (conductive) geothermal systems

Static geothermal systems depend on above-average conductive heat flow in the crust. In static magmatic systems, fluids can be heated by granitic plutons. Other conductive systems are hosted by porous sedimentary rocks in deep sedimentary basins. Static systems generally have little impact at the surface. However, trapped formation waters, which are typically saline, chloride-rich and have temperatures of ~ 70 – 150°C , can be released by tectonic movements and discharge at the surface as thermal springs with variable temperature and salinity, depending on the degree of mixing with shallow groundwaters. Many examples are known from Europe, especially Germany (Kühn, 2004).

Dynamic (convective) geothermal systems

Most high-temperature geothermal systems are linked to magmatic intrusions (volcano-plutonic and volcanic), which provide the heat that drives the convective circulation. In such systems, reservoir temperatures are commonly $>150^\circ\text{C}$ at depths of a few kilometers. Such systems are most common in sites of geologically young volcanism and in tectonically active regions such as areas of faulting, rifting, and caldera collapse, and at plate

margins in general. As in other hydrothermal systems, the waters are predominantly meteoric, and the ascending fluids commonly boil before or during surface discharge. The hydrothermal systems vary with tectonic location and type of volcanism (Pirajno, 1992). Many are associated with silica-rich and andesitic volcanism, whereas others are associated with basaltic volcanism.

Silica-andesitic systems

High-temperature hydrothermal systems associated with silica-rich volcanism are highly variable. Some systems are liquid dominated, producing springs and geysers, whereas others are vapor dominated, generating mainly steaming ground and fumaroles at the land surface.

In regions of low relief (Figure 3a), magmatic systems supply heat and gases to meteoric groundwater and give rise to convective columns that can allow deep chloride-rich waters to flow directly to the surface (e.g., Taupo Volcanic Zone, New Zealand). The deep fluids may discharge as springs and geysers above the main upflow or may move laterally some distance away from upflow column. Steam zones commonly develop in sites marginal to the main upflow. Oxidation of H_2S and other gases in groundwater produces acid sulfate waters, generating fumaroles and steaming ground. Condensation of CO_2 in groundwater may produce neutral to alkaline bicarbonate springs around the margins of the field from which travertine may be formed. These types of system commonly have fumaroles, steaming ground, and both acid and alkaline springs located near each other because of the low topographic relief and limited potential for lateral flow of fluids near the land surface.

In areas of high relief (Figure 3b), such as andesitic stratovolcanoes, a thick two-phase zone (liquid–steam–gas) commonly develops below the land surface. At high elevations, fumaroles, steam vents, and acid sulfate springs fed by condensate are common features. Deep chloride-rich waters normally do not reach the surface but may flow laterally and mix with groundwater or cooled, descending sulfate waters before discharging as hot springs on the volcano flanks or other areas of relatively low relief. Numerous examples are found in Indonesia, the Philippines, and Japan.

Some silicic systems are vapor dominated (e.g., Lardarello, Italy; The Geysers, California). The deep thermal reservoir contains steam, probably fed by saline boiling water, most of which is contained in convective cells capped by low-permeability rocks. Fluids escaping the reservoir produce steaming ground and fumaroles at the surface and some thermal springs similar to those in high-relief regions. Surface fluids can be of acid sulfate or bicarbonate type.

Basaltic systems

High-temperature basaltic systems occur at mid-oceanic ridges (see Chapter *Hydrothermal Environments, Marine*) and in continental rifts. Many tectonic and hydrogeological settings are possible (Pirajno, 1992), but

in most examples hydrothermal fluids rise along permeable faults discharging at hot springs and geysers on the rift basin floor (Figure 2c), including subaqueous discharge on the floors of lakes. Fluid compositions are variable and depend partly on the bedrock composition, which may be volcanic, basement rocks, or valley-fill sediments.

Low temperature systems

Low-temperature geothermal systems are common and of diverse origins. Most are characterized by dilute waters that are discharged as springs with maximum temperatures of about 30–60°C. They form in regions of both normal and above-average heat flow. They are common where meteoric fluids return to the surface having been heated to temperatures above ambient surface temperature. These springs commonly occur in regions of deep faulting and folding, in regions of tectonic uplift where hot rocks have been elevated to higher levels in the crust, and from the residual heat of cooling plutons (Nicholson, 1993). Meteoric fluids circulate at depth through faults, fractures, and permeable rocks. The chemical composition of the fluids reflects such factors as the bedrock mineralogical composition, depth and temperature of fluid circulation, the rates of recharge, and degree of mixing with near-surface waters before discharge. Such low-enthalpy systems are common in western Canada, Europe, Australia, and on most continents.

The surface environment in hydrothermal areas

Areas of hydrothermal discharge are distinctive features of the landscape. Where they are extensive, they can influence the local ecology at all scales, from large mammals to microbes. The impact of hydrothermal discharge at the land surface ranges from negligible, where dilute warm springs flow quietly from small vents at temperatures little above ambient, to major, where high-temperature and acidic fluids destroy vegetation, precipitate mineral deposits, or flood the landscape. In general, areas of neutral to alkaline hydrothermal discharge are mainly constructive with new rocks (sinter, travertine, and others) precipitated from hydrothermal fluids upon an existing landscape (Figure 2a, c). In contrast, where the fluids are mainly acidic, the net impact on the surface environment is often destructive and the landscape commonly becomes nearly barren and pock-marked by craters that result from collapse due to hydrothermal alteration of the host bedrock or hydrothermal explosions (Figure 2b, d). The main hydrothermal surface features are hot springs and geysers, fumaroles, steam vents, and mudpots. Some hydrothermal springs also discharge on the floors of lakes.

Hot springs

Hot springs are sites where geothermally heated groundwater discharges at the land surface (see Chapter *Hot Springs and Geysers*). There is no universally accepted definition of a hot spring (Pentecost et al., 2003). Some definitions place the lower temperature limit at an

arbitrary value (e.g., human body temperature: $\sim 37^{\circ}\text{C}$; or some fixed value: 20° , 35° , 50°C , etc.), whereas others define a hot spring by its temperature relationship to local ambient surface water temperature, mean air temperature, or a similar environmental factor. As generally used, the term hot spring is given to those springs that discharge at between $\sim 35^{\circ}\text{C}$ and the local boiling point.

Individual hot springs vary greatly in size (<10 cm to ~ 80 m in vent diameter), depth, shape, and discharge. The most common forms are circular and subcircular pools where water flows from poorly consolidated sediments or hydrothermally altered ground (Figure 4a). Very large hot springs include Grand Prismatic Spring at Yellowstone National Park and Champagne Pool at Waiotapu in New Zealand. Some large springs are composite with multiple vents discharging into a single basin (e.g., Frying Pan Lake, Waimangu, New Zealand). In contrast, shape and size can be highly irregular where flow emanates from a resistant substrate such as volcanic bedrock or from faults and fractures (Figure 4b, c). In the latter case, for example, the vents may be linear fissures without a pool. The vent morphology may change through time as pools coalesce or contract with changes, for example, in surface discharge and earthquake activity.

Geysers (Figure 4d) are hot springs characterized by intermittent turbulent discharge of water that is induced by a vapor phase of gases (mainly steam) that results from boiling. Geysers are rare (Figure 1), with more than 50% of all known geysers in Yellowstone National Park, Wyoming, USA (Bryan, 2005). Well-known geysers include Geysir in Iceland (eponym for geyser) (Torfason, 1985), Old Faithful in Yellowstone National Park (Bryan, 2008), and Pohutu at Whakarewarewa in New Zealand (Jones and Renaut, 2003b). Intermittent springs flow periodically but discharge quietly and lack the forceful ejection of a true geyser. Some springs, termed perpetual spouters (Figure 4e), erupt jets of water and steam constantly, but lack the periodicity of geysers.

Springs also change in morphology as minerals are precipitated in and around their vents (see Chapter Sinter). Mineral precipitation commonly begins around pool margins with build up of a pool-rim dam (Figure 4a), which, depending on hydrostatic pressure, may raise the water level. Water overflowing the dam may then precipitate minerals to form terraces (rimstone dams and pools), oncoids, pisoids, and a range of other spring deposits (Jones and Renaut, 2003a; Pentecost, 2005). At some springs, including many geysers, vents may grow upward forming a range of conical mound deposits (Figure 4d). Microorganisms are commonly fossilized in the spring deposits, and some have been implicated in mineral precipitation.

Fumaroles (steam vents) and mudpots

Fumaroles are vents or openings in the ground that discharge hot water vapor (steam) and (or) volcanic gases. Fumaroles are common features of active volcanoes,

where they can attain temperatures of $>900^{\circ}\text{C}$, but much cooler ($<150^{\circ}\text{C}$) vents are also present at dormant and recently extinct volcanoes and at some high-temperature spring sites, mainly in areas where the water table is relatively low. Fumaroles emit mainly steam (typically $>90\%$), carbon dioxide, and lesser amounts of sulfur (especially H_2S) and chlorine compounds. Minor carbon monoxide, ammonia, boron and fluorine compounds are present in some gases. The predominant steam is mainly superheated groundwater, whereas much of other gas is magmatically sourced. *Solfataras* are areas where fumaroles discharge large volumes of sulfur gases; *mofettes* discharge carbon dioxide, sometimes methane, from fumaroles at temperatures below boiling point of water but above those of ambient air. Mofette gases trapped in valleys and depressions can cause asphyxiation.

The impact of fumaroles on the landscape and environment reflects their abundance, gas composition, temperature, and location. Fumaroles can form on steep and low-angled slopes. On steep slopes, they typically emerge from cracks in the substrate, cm to m in scale, which may be linear, irregular, or funnel-shaped openings where gases have hydrothermally altered the bedrock. On low ground, fumaroles may pockmark the landscape with series of pits (Figure 4f), some meters in diameter. Minerals (*fumarolites*) are commonly precipitated around the vents as rock coatings, many of which are sublimates from the fumarole gases. This diverse array of minerals includes opaline silica, native sulfur, jarosite, Fe-oxyhydroxides, and many salts and rare minerals, some incorporating volatiles.

Rising steam and gases may heat the ground and condense near the land surface or may heat groundwater at shallow depth. The condensed steam and heated water may boil at the water table to produce areas of steaming ground. If H_2S is present in the vapor phase, the resulting sulfuric acid commonly attacks the bedrock and soils and may generate abundant clay minerals, especially kaolinite, producing mudpots (Figure 4g). Forceful eruption of viscous mud can produce mud volcanoes (Figure 4h). The mineralogy of mudpots has received little attention, but includes a similar suite of minerals to other acid sulfate springs.

Steam (hydrothermal) explosions

The surface environment at high-temperature hydrothermal sites occasionally undergoes major disturbances due to hydrothermal eruptions. Such eruptions have several causes but are typically related to the inability of the plumbing system to withstand high fluid pressures generated by boiling. Most eruptions result from the rapid generation of steam due to a sudden pressure reduction (Browne and Lawless, 2001). The explosive release of vapor may lead to break up of sinter or other rocks near the land surface. Blocks become strewn across the landscape, new vents may be formed, and old vents may become inactive because of the changes in the subsurface plumbing system.

Hydrothermal Environments, Terrestrial, Figure 4 Surface features in terrestrial hydrothermal environments. (a) Hot spring with sinter pool-rim dam. Oyster Pool (pH 4.5; T: 65°C), Waiotapu, New Zealand. (b) Hot spring (pH 8.8; 99°C) emerging from fractured trachyphonolite bedrock at Chemurkeu, Lake Bogoria, Kenya. (c) Low-enthalpy, dilute bicarbonate hot spring (pH: 6.6; T: 36°C) at Lobo, Lake Bogoria, Kenya. (d) Clepsydra Geyser, Yellowstone National Park. (e) Perpetually spouting hot spring (pH: 8.7; T: 98.5°C) with mound of subfossil travertine, Lake Bogoria, Kenya. (f) Large (3 m wide) fumarole vent at Sol de Mañana geothermal field, southern Bolivia. (g) Boiling mudpool at Sol de Mañana geothermal field, southern Bolivia. (h) Mud volcano, Tikitere, near Rotorua, New Zealand.

The Waimangu geothermal area on North Island, New Zealand, experienced major hydrothermal explosions on April 1, 1917 that created Frying Pan Lake, with further eruptions in 1924 and 1973 (Lloyd and Keam, 1974). The 1973 eruption, for example, distributed ejecta, which consisted of hydrothermally-altered angular blocks of country rock (up to 30 cm diameter) and fine debris, over an area of $\sim 3 \text{ km}^2$.

Sublacustrine hydrothermal discharge

Thermal fluids can discharge directly from lake floors either as underwater springs or as steam and gas vents. Diffuse upward-moving steam and gases may also condense in lake water through permeable sediments without point-sourced vents. Sublacustrine springs are most common on the floors of caldera (crater) lakes, continental rift, and other tectonic lakes, and in lakes produced by subsidence, collapse, or hydrothermal eruptions in areas of acidic hydrothermal discharge. Their impact on life in the lake depends on the respective chemistry and temperatures of the lake water and thermal fluids, the rate and volume of thermal fluid discharge, and lake size, morphology, and climate, which can control seasonal stratification and hydrological closure. Like submarine springs, sublacustrine hot springs may host local communities of thermophilic organisms, and biofilms or microbial mats commonly cover the vent surfaces. Sublacustrine sinter, travertine (tufa), and other mineral deposits (e.g., metal sulfides) can precipitate around vents at sites where thermal fluids mix with lake water, undergo cooling, or exsolve noncondensable gases. Spring deposits include spires, chimneys, mounds, crusts, and various microbialites. Sublacustrine spring deposits commonly incorporate lacustrine organisms, especially planktonic diatoms and freshwater sponges, which can help distinguish them from morphologically similar subaerial spring deposits when examining ancient deposits.

Well-known examples of sublacustrine spring systems include those in Crater Lake (Oregon), Yellowstone Lake (Wyoming), Lakes Tanganyika, Kivu and Bogoria in the East African Rift, and Lake Taupo (North Island, New Zealand). Hot springs on the floor of Lake Taupo at depths of $\sim 140 \text{ m}$, for example, have produced small chimneys formed of opal-A and various Mn-, Fe-, and Hg-precipitates (de Ronde et al., 2002). Crater lakes in active and dormant volcanoes commonly receive discharge from acidic springs and fumaroles that produces acid lake waters.

Life in terrestrial hydrothermal environments

Terrestrial hydrothermal environments host many organisms, but some, notably thermophiles ($\sim 45^\circ\text{--}80^\circ\text{C}$) and hyperthermophiles ($>80^\circ\text{C}$), are unique to hydrothermal settings (see Chapter *Extreme Environments*). Although the ecology of hydrothermal environments has been studied extensively (e.g., Brock, 1978; Reysenbach et al., 2001; Robb et al., 2007; Wiegand, 2007), new discoveries continue to be made regularly. The distribution of microorganisms at hot springs and geysers is controlled mainly by temperature, pH, and water chemistry. Brock (1978) first established the main temperature tolerance ranges for the main groups of organisms in hot-spring systems (Figure 5).

Proximal areas under the influence of near-boiling water ejected from hot springs and geysers were once regarded as being sterile. The ornate and banded silica deposits commonly found around geyser vents were named “geyserite” because they were thought to have formed abiotically (Walter, 1976). It has since been shown that a diverse community of microorganisms inhabit these very hot waters (Blank et al., 2002) and that geyserite commonly contains abundant silicified microbes (Jones et al., 1997). Identifying these microbes is a challenge because many are difficult to culture and their

Hydrothermal Environments, Terrestrial, Figure 5 Upper temperature tolerance limits of selected organisms in hydrothermal environments (modified from Brock, 1978).

morphological diversity is low. DNA analyses, however, show that these extremophiles are biologically diverse (Barns et al., 2004). The hyperthermophiles are dominantly archaea, and some are also thermoacidophiles. In the hottest (anoxic) waters, the archaea are mainly chemolithoautotrophs and chemoorganotrophs, and include coccoid, rod-shaped, and filamentous forms (e.g., *Pyrolobus*, *Pyrococcus*, *Methanothermus*). Hyperthermophilic bacteria (e.g., *Aquifex*, *Geothermobacterium*), some of which are sulfide and hydrogen oxidizing species, also thrive in waters up to boiling point. Viruses also inhabit these high-temperature settings. Thin microbial films locally coat immersed rock and soil surfaces around the edge of the vents (Figure 6a), and filamentous stringers of hyperthermophiles are sometimes seen attached to the substrate in proximal outflow channels.

As water temperature decreases downstream from the spring and geyser vents, the species diversity usually increases. At temperatures between 75 and $\sim 40^{\circ}\text{C}$, microbial mats are commonly well developed in neutral and alkaline waters (Figure 6b). Varicoloured (green, orange, brown) microbial mats built by photosynthetic cyanobacteria often cover the substrate in sites that remain almost constantly moist from thermal outflow, and are commonly several cm thick (Figure 6c). Small coniform stromatolites form in some low-energy pools (Figure 6d, e) (Jones et al., 2002). Common genera include *Oscillatoria*, *Synechococcus*, *Phormidium*, *Anabaena*, and *Spirulina*. *Chloroflexus*, a green sulfur bacterium and anoxygenic photoautotroph, is commonly associated with these mats. Extensive extracellular polymeric gels are produced by some of these communities. Heterotrophic bacterial communities normally underlie the surface layers of these mats (Brock, 1978). Organisms common in waters cooler than $\sim 45^{\circ}\text{C}$ include the cyanobacteria *Calothrix* and *Pleurocapsa*, which often build nodular mats, eukaryotic algae, diatoms, fungi, and protists, some of which become important components of microbial mats.

Acid thermal areas, including areas around some fumaroles (and solfataras), usually have distinctive acidophilic communities. In acidic hot springs where the temperature is $<60^{\circ}\text{C}$, green mats built by the unicellular red alga *Cyanidium caldarium* are often present (Figure 6f) (Brock, 1978), together with a range of bacteria (e.g., *Thiobacillus*). Below pH 5, cyanobacteria are less abundant and mats composed of diatoms and fungi become common. Stromatolitic sinters built by diatoms, for example, are present at Frying Pan Flats at Waiotapu, New Zealand, where the pH is <3 (Figure 6g) (Jones et al., 2000).

Invertebrates, such as mat-grazing ostracods, are common in some hot spring waters that are $<45^{\circ}\text{C}$. Insects are common at some hot springs and include spiders, beetles, and flies. Adult and larval *Ephydrya* spp., for example, feed on microbial mats in hot spring effluent (Figure 6h). Few vertebrates are restricted to thermal aquatic environments, but fish (*Alcolapia grahami*) inhabit hot spring pools with temperatures up to 46°C at Lake Magadi, Kenya (Figure 6i).

Environmental impact of terrestrial hydrothermal activity

The environmental consequences of terrestrial hydrothermal activity are highly diverse, as a few examples can illustrate. High concentrations of metals such as As that are present in effluent can be absorbed by vegetation in thermal areas with variable effects (Koch et al., 1999). High concentrations of fluoride in dilute hot-spring outflow are a problem (fluorosis) for animals and humans in parts of China, Kenya, Tanzania, and elsewhere (e.g., Xu et al., 1995). Toxins in thermophilic cyanobacterial mats have been blamed for deaths (e.g., Krienitz et al., 2003) of birds. Fumarole gases are commonly toxic and have killed animals and vegetation in many locations (e.g., Baxter et al., 1999). Effluent from geothermal sites can contaminate freshwater aquifers and surface waters. In many cases, the impact of hydrothermal activity is negative from a human perspective, but this is partly balanced by the strong appeal of hot springs, geysers, and fumaroles as tourist attractions.

Temporal and anthropogenic changes in hot spring and geyser activity

Hydrothermal features at the land surface are typically ephemeral, with activity lasting from months up to several hundred thousand years (see Chapter *Hydrothermal Environments, Fossil*), but renewed activity may recur at the same location following volcanic and tectonic events (e.g., faulting) or climate change. Hot springs, geysers, and fumaroles may continue to function provided the basic requirements of a heat source, reliable fluid source, and permeable fluid pathway to the surface are met. Variations in heat source typically occur over long timescales (e.g., magmatic cooling), but water supply and fluid pathways (permeability) to the land surface can vary over much shorter timescales and induce frequent and shorter-term changes in hydrothermal activity.

The fluid recharge is especially sensitive to climate. Sturchio et al. (1993), for example, showed that periods of sinter formation in the arid northern Kenya Rift during the Pleistocene could be correlated with phases of humid climate. Springs that discharged chloride waters and precipitated sinter when water tables were regionally high during wetter periods are now acidic fumaroles or have become extinct. Even very short-term climate changes can have an impact. The activity of geysers and hot springs on the shoreline of Lake Bogoria in Kenya, for example, responds rapidly to minor changes in lake level (<30 cm) that are induced by El Niño rains (Renaut et al., 2005).

Anthropogenic activity can also cause substantial changes to the level of the water table over periods of a few years, as examples from New Zealand demonstrate. Development of the Wairakei geothermal power plant in the late 1950s led to a large fall in the water table, subsidence, and the loss of at least 100 geysers (Glover, 1965; Bryan, 2008). Decreasing geyser activity and other

Hydrothermal Environments, Terrestrial, Figure 6 Life in terrestrial hydrothermal environments. (a) Vent of small geyser (former well bore) at Tokaanu, New Zealand. Despite the boiling water spray and overflow, a diverse microbial community inhabits the area at the vent and their remains are fossilized in the sinter. (b) Thick (up to 10 cm) microbial mats near the vent of a perpetually spouting, Na-HCO₃ hot spring at Lake Bogoria, Kenya (shown in Figure 2c). The mats (*Chloroflexus* and several cyanobacterial species) receive spray from the spring but are absent where water temperature is constantly >70°C. (c) Microbial mats (cyanobacteria) in shallow outflow (pH: 8.8; T: 40–85°C) from a Na-HCO₃ hot spring at Lake Bogoria, Kenya. (d), (e) Small coniform stromatolites, built by *Phormidium* growing in Kirihero spring pool (pH: 7.5; T: 38°C), Tokaanu, New Zealand. (f) Green subaqueous *Cyanidium* mats adjacent to glassy spicular sinter in an acidic (pH 2.6; T: 48°C), shallow spring pool near Hakereteke Stream, north Waiotapu, New Zealand. (e) along the edge of a small alkaline hot spring (v) (pH: 8.6; T: 47°C), Lake Magadi, Kenya. The ephydrids feed on the mats on the discharge apron. (i) *Alcolapia grahmi* swimming in the vent pool (pH: 9.9; T: 46°C) of an alkaline hot spring, Lake Magadi, Kenya.

changes in the Whakarewarewa geothermal area over several decades have been attributed to natural changes in the subterranean plumbing system and to increased water extraction in nearby Rotorua.

The history of Geysir in Iceland is known from 1,294 AD because its behavior has been recorded in Icelandic literature. Historical sources show that the geyser activity has varied considerably, with periods of regular discharge alternating with periods of quiescence with eruptions. At Geysir, earthquakes rather than climate variability often seem to cause changes in its patterns of eruption (Torfasen, 1985; Jones et al., 2007).

In some instances, changes in the subsurface aquifer and plumbing systems may trigger renewed activity after years of inactivity. The sudden, renewed activity of hot springs in residential areas can, for example, have a radical impact. This has happened recently (2000–2001) in Rotorua, New Zealand, where house owners awoke to find hot springs and mudpools in what used to be their back gardens, and a hydrothermal eruption (February 2001) sent mud 100 m into the air and created a pool 10 m in diameter in a local park.

Conclusions

Terrestrial hydrothermal environments occupy a small percentage of the Earth's surface but they provide a wealth of information on both geological and biological processes. These environments cover almost the entire spectrum of pH (0 to >10 in some alkaline hot springs) and water temperature range, and it is commonly possible to examine alkaline and highly acidic environments within a few kilometers of each other. For the geologists, they provide clues to mineral–water reactions occurring below the Earth's surface and the origin of some ore minerals. For the biologists, they provide opportunities to study a wide range of extremophiles in natural environments that, with care and permission, are generally accessible. With the discovery of possible siliceous hydrothermal deposits and highly acidic environments on Mars, the scientific interest in these environments is currently high and is likely to continue.

Synonyms

Aurum (Latin)

Definition

Precipitation/Bioaccumulation of gold is the precipitation of fine-grained gold colloids by microbial activities.

Nugget. A natural gold grain (>5 mm, >200 mg).

The impact of the use of microbial activity for the solution and precipitation of gold was undervalued for a long period, thus affording the opportunity for economic and environmentally friendly gold bio-processing. Furthermore, the current high price of gold has led to intensive research into the precipitation of gold.

Some iron and sulfur oxidizers (e.g., *Acidothiobacillus ferrooxidans*, *Acidithiobacillus thiooxidans*) contribute to the disintegration of important gold ores (Nordstrom and Southam, 1997). In an environment of gold-bearing rocks, the dissolved gold content is 40 times higher than in comparable non-gold-bearing areas (Benedetti and Boulègue,

1991). It has been shown that the dissolution of gold is dominated by the gold thiosulfate complex $\text{Au}(\text{S}_2\text{O}_3)_2^{3-}$ which is composed of the above-mentioned bacteria and Actinomycetes (e.g., *Streptomyces fradiae*) (Nordstrom and Southam, 1997; Sand et al., 2001). However, $\text{Au}(\text{S}_2\text{O}_3)_2^{3-}$ is only stable until the sulfur-oxidation is complete (Lengke and Southam, 2005). Subsequently the gold thiosulfate complex is degraded by *A. thiooxidans*. Thereby gold accumulates in the form of fine-grained colloids inside the bacterial cell and on the surface of the cell membrane. Comparable with the results of Southam and Beveridge (1996) with *Bacillus subtilis* 168, hexagonal-octahedral gold crystals are generated out of the colloids after some months (Figure 1).

As a result of the toxicity of an increasing content of ionized gold, most of the microorganisms that can generate gold die on accumulation of gold. However, various microorganisms, such as bacteria (e.g., *Escherichia coli*, *Pseudomonas maltophilia*, *Plectonema boryanum*), Archaea (e.g., *Pyrococcus furiosus*), Actinomycetes (e.g., *Streptomyces cinamonensis*), fungi (e.g., *Neurospora sitophila*, *Fusarium oxysporum*) and yeasts (e.g., *Endomycopsis fibuligera*, *Sporobolomyces salmonicolor*) from different environments (e.g., hydrothermal, supergene), are partially resistant to the toxicity induced by the accumulation of gold (Kashefi et al., 2001; Nakajima, 2003; Lengke et al., 2006). These bioaccumulation processes are related to various microbial activities (e.g., detoxification, energy generation, passive adsorption). In the laboratory, *Pseudomonas aeruginosa* biofilms demonstrate a higher resistance to the toxicity of gold than planktonic *P. aeruginosa* cells and form solid gold at the base of the biofilms (Karthikeyan and Beveridge, 2002). Reith et al. (2006) isolated a 16SrDNA sequence from natural samples. This sequence was only found on gold grains

and not in the surrounding sediments. With a similarity of 99%, the sequence correlated to *Cupriavidus (Ralstonia) metallidurans*. Ninety percent of the bacteria in the laboratory experiment died because of the toxicity of AuCl_4^- . The surviving cells adapted themselves to the high concentration of Au(III) ions and precipitated gold. In addition to morphological studies (Bischoff, 1997), this provides evidence for bioaccumulation of secondary gold (e.g., nuggets, gold grains) by bacteria like *C. metallidurans* (Figure 2).

The basal biochemical microbial processes of the biomineralization of gold are not completely understood yet. Precipitation of gold provides the cellular defense of *C. metallidurans* and is controlled by a coupling of efflux, reduction and possibly methylation of gold complexes (Reith et al., 2009). Reith et al. (2007) have published a comprehensive review of the geomicrobiology of gold.

Summary

Different microorganisms are partially resistant to dissolved gold. Various microbial activities precipitate gold. Biofilms of *Cupriavidus metallidurans* accumulate gold naturally and contribute to the formation of secondary gold.

GONDWANALAND, FORMATION

Joseph G. Meert
 University of Florida, Gainesville, FL, USA

Definition

Gondwanaland or “Gondwana” is the name for the southern half of the Pangaeon supercontinent that existed some 300 million years ago. Gondwanaland is composed of the major continental blocks of South America, Africa,

H

HABITAT

The physical location or dwelling place of a particular organism, where an individual ecotype can be found or isolated from. See entry “*Microbial Communities, Structure, and Function*” for further reading.

HALOBACTERIA – HALOPHILES

Helga Stan-Lotter
University of Salzburg, Salzburg, Austria

Definition

Halobacteria (plural), *halobacterium* (singular). Colloquial for halophilic archaeobacteria (or archaea), which are single-celled life forms. Synonyms: Haloarchaea (plural), haloarchaeon (singular).

Halobacterium. The name of a genus of the archaeal family *Halobacteriaceae* (Grant, 2001).

Halophilic. Requires a salt-rich environment for growth and survival.

Introduction

Saline waters dominate the earth, with the oceans holding 97% of the planet's water (a total of 1.338×10^9 km³; <http://ga.water.usgs.gov/edu/earthwherewater.html>). Saline inland seas, groundwater, and saltwater lakes hold another 0.9–0.94%, which exceeds the volume of the world's available freshwater ($\sim 1.1 \times 10^7$ km³). The definition of a hypersaline environment is one that possesses a salt concentration greater than that of seawater (>3.5% w/v). Water-containing environments are usually described as thalassohaline or athalassohaline (see

Chapters “*Saline Lakes*,” “*Soda Lakes*”). Thalassohaline waters are marine-derived and therefore contain, at least initially, the seawater composition; with increasing evaporation, the concentration of various salts is changing. Athalassohaline waters may also receive influx of seawater; however, the chemical composition is mainly determined by geological, geographical, and topographical parameters.

Interactions between halophilic microorganisms and geological materials have been recognized early in the history of mankind and continue to impact human endeavors, including the exploration of energy sources, the storage of waste, the search for extraterrestrial life (see Chapter “*Deep Biosphere of Salt Deposits*”). For example, the evaporation of seawater for the purpose of making salt and the concomitant development of red color of brines, which is due to pigmented microorganisms, have been described already 2,700 years ago (Oren, 2002). It was also observed early that the presence of microorganisms in solar salterns enhances the precipitation and the yield of salt (Oren, 2002). Halite, the mineral of sodium chloride, primarily forms from the evaporation of seawater. Subsurface deposits of halite occur in many areas and are far more abundant than was previously recognized. The advent of widespread oil drilling revealed a frequent association of ancient salt deposits and the presence of the biogenic energy sources, oil and methane (Sassen et al., 1994). The potential impact of viable halophilic microorganisms in salt deposits (see Chapter “*Deep Biosphere of Salt Deposits*”), some of which are being used as storage sites for long-lived radioactive isotopes such as transuranic wastes, has been the focus of much research. The striking discovery of extraterrestrial halite in meteorites (see Chapter “*Deep Biosphere of Salt Deposits*”) and recently, in salt pools on Mars (Osterloo et al., 2008) make a search for halophilic microorganisms on other planets or moons plausible.

Saline environments and their inhabitants

Organisms occur within a range of salinities, from distilled water to saturated salt solutions, and may be loosely classified as non-, slightly, moderately, or extremely halophilic, requiring about 0.2 M, 0.2–0.85 M, 0.85–2.5 M, and 2.5–5.2 M NaCl, respectively, for growth. The largest saline environment, seawater, contains 31–38 g of total dissolved salts per liter, nearly 80% of which is NaCl. Hypersaline environments are characterized by higher salinities than seawater. The oceans are inhabited by a great diversity of organisms; when seawater is evaporating, the biological diversity decreases with increasing concentration of salt. Macroscopic organisms such as salt-tolerant fish (e.g., *Cyprinodon variegatus* and *Menidia beryllina*) are no longer found at concentrations of more than about 11% salt (1.88 M NaCl); copepods (fleas), turbellarian worms, and some rotifers tolerate 15–17% salt. Interestingly, several invertebrates such as brine shrimp (*Artemia salina*) or brine flies (*Ephydra cinerea*) are capable of survival at NaCl concentrations of 30–33% (~5 M; Javor, 1989). However, the dominating organisms in saturated brines are extremely halophilic microorganisms which grow optimally in the presence of 2.5–5.2 M NaCl and are generally unable to grow in less than 1.7 M NaCl. They can occur at such high cell densities (up to 10^8 colony forming units per milliliter) that they cause brines to turn bright red or purplish. Figure 1 shows a commercial salt-producing facility where seawater is evaporating in a series of ponds. The colors of the pools are caused by carotenoid pigments, which are contained in the membranes of haloarchaea, or by the chlorophylls of halophilic algae or cyanobacteria. Typical haloarchaea in such communities are species of the genera *Halobacterium*, *Halorubrum*, and *Halococcus*, halophilic bacteria such as *Ectothiorhodospira halochloris*, *Salinibacter ruber*, cyanobacteria (e.g., *Aphanothece halophytica*, *Phormidium* sp. and *Schizothrix arenaria*), and green algae (e.g., *Dunaliella salina* and *Asteromonas*

gracilis). Figure 2 shows two characteristic haloarchaeal morphologies – *Halobacterium salinarum* NRC-1 grows as single rod-shaped cells; *Halococcus salifodinae* cells are roundish and tend to aggregate into large clusters.

Crude solar salt contains large numbers of viable bacteria and archaea (about 10^5 – 10^6 colony forming units per milliliter; Oren, 2002). When using this salt for the preservation of fish, meat, and hides, damage in the form of red discoloration of the goods was noted under conditions of moisture and elevated temperatures. These observations started the early research on halophilic microorganisms in the 1920s–1930s. Only much later – in the 1980s – was it recognized that most halophiles from such sources belonged to the archaea. The haloarchaea are not pathogenic; in fact, some are used in traditionally fermented foods in Asia for human consumption (Oren, 2002).

There exist other hypersaline environments which are not directly derived from seawater and are called athalassohaline (see above and Chapter “Soda Lakes”); often they are remnants of prehistoric inland lakes, such as the Dead Sea and the Great Salt Lake. Additional larger lakes include Mono Lake in California, soda lakes in Egypt and China, Lake Magadi in Kenya, and Lake Eyre in Australia. The chemical composition varies depending on the geology of the surroundings, but overall salinity is usually between 200 and 340 g/l of dissolved salts. Soda lakes are an example of naturally occurring alkaline environments which may also be hypersaline, and are characterized by the presence of large amounts of sodium carbonate and correspondingly minute concentrations of Ca^{2+} and Mg^{2+} . The pH of alkaline lakes is usually in the range of 10–11; in some evaporation ponds, it can rise up to 12 (Oren, 2002). Microbial isolates from alkaline hypersaline lakes include the archaea *Natronomonas* sp., *Natronococcus* sp., *Natrialba* sp., and bacteria of the genera *Halomonas*, *Chromohalobacter*, *Spirulina* (the latter is known as nutrient for humans and animals) and others still to be characterized (Javor, 1989; Oren, 2002).

Halobacteria – Halophiles, Figure 1 Lagoons of a commercial salt-producing facility in Namibia, close to the ocean. Red-colored lagoons contain mainly haloarchaea; green color is due to halotolerant algae or cyanobacteria.

Halobacteria – Halophiles, Figure 2 Scanning electron micrograph of cells of *Halobacterium salinarum* NRC-1 (left) and *Halococcus salifodinae* DSM8989T (right). Bars, 0.5 μm. (Photographs were taken by C. Frethem (left) and G. Wanner (right).)

From the Deep Lake in the Vestfold Hills of Antarctica, a psychrophilic archaeon, *Halorubrum lacusprofundi*, was isolated. Deep Lake has a salinity that is ten times higher than that of seawater (3.6–4.8 M). The lake remains ice-free throughout the year, with water temperatures fluctuating between +10 and –15°C and remaining below 0°C for ~8 months of the year. The microbial diversity in Deep Lake is extremely low and is dominated by haloarchaea, with apparently low numbers of *Dunaliella* sp. and bacteria (of the beta- and gamma-proteobacteria) present in the sediment (Cavicchioli, 2006).

Less explored and unusual hypersaline habitats are represented by anoxic brines near the bottom of the sea, for example in the Mediterranean deeps, which contain saline brines almost saturated with magnesium chloride, and where a wide diversity of novel archaea and bacteria was detected (van der Wielen et al., 2005).

Another environment for halophilic microorganisms are ancient salt deposits; recent reports have described the presence of haloarchaea in Triassic and Permian salts (summarized in McGenity et al., 2000; Stan-Lotter et al., 2004). These viable microorganisms were consistently isolated from surface-sterilized crystals obtained from freshly blasted rock salt or deep drilling bore cores, suggesting that these were survivors from the original depositional event (see Chapter “*Deep Biosphere of Salt Deposits*”).

Finally, halophilic viruses have been detected, which were released from bacteria and archaea; in addition, free virus particles were found by electron microscopical examination of the Dead Sea and in Spanish saltern ponds (Oren, 2002). The viruses (also called bacteriophages) were equally dependent as their hosts on high concentrations of salt for their structural stability. There is little information on the role of viruses in natural environments; suggestions which were made involve ecological functions in controlling the sizes of microbial communities (Oren, 2002). A website with pictures of haloviruses from

the laboratory of M. Dyll-Smith is available: <http://www.microbiol.unimelb.edu.au/people/dyallsmith/research/haloviruses/>

Classification and genomics

Halophilic means salt-loving and this term, often as the prefix hal- or halo-, has been in use since the 1930s. Therefore, members of the bacteria as well as the separate prokaryotic group archaea, which was identified only in the 1970s, may contain such prefixes in their names. Some confusion may arise from this nomenclatural convention, since, for example, the genus with the name *Halobacterium* belongs to the halophilic archaea (or haloarchaea), not to the bacteria.

The number of recognized haloarchaeal genera has increased to 26, according to the International Committee on Systematics of Prokaryotes (<http://www.the-icsp.org>) and the number of validated species at this time is 86. Main taxonomic criteria for the identification and recognition of haloarchaea are the sequence of the 16S rRNA genes and the composition of their characteristic membrane polar lipids, which are unique ether-linked phosphoglycerides (see Fendrihan et al., 2006, for a recent overview). The complete list of required and recommended criteria for the formal identification and recognition of haloarchaeal species was proposed by Oren et al. (1997). For halophilic bacteria belonging to the large family *Halomonadaceae*, a similar list of specific characteristics, which has been revised recently, can be consulted (Arahal et al., 2007).

Five genomes of haloarchaea have been completely sequenced, that of *Halobacterium salinarum* NRC-1, the related strain *Halobacterium salinarum* R1, *Haloarcula marismortui*, *Natronomonas pharaonis*, and *Haloquadratum walsbyi*, and one genome of a halophilic bacterium (*Salinibacter ruber*). The website <http://www.ncbi.nlm.nih.gov/sites/entrez> lists all genome projects, whether complete or still in progress, including references

and detailed descriptions. Comparisons of genomes continue to provide insights about similarity and differences between archaea and bacteria and about the early evolution of prokaryotes. They have, for example, proven that the adaptation mechanism of keeping a high internal salt concentration (see next paragraph) is not unique to archaea, as was thought before, but is used also by *Salinibacter ruber*; this common property as well as some other characteristics suggests the possibility of early lateral gene transfers between prokaryotes (Velieux et al., 2007).

Adaptations to high salinity

Most halophiles are unable to survive outside their high-salt native environments. Some species of the haloarchaea are so fragile that when placed in distilled water they lyse within minutes from the change in osmotic conditions (Grant, 2001). This reflects a general adaptation of the cells' entire intracellular machinery to high concentrations of cations. Halophilic and halotolerant organisms have to expend energy to exclude salt from their cytoplasm to avoid protein aggregation ("salting out"). Two different strategies are known to be used to prevent desiccation through osmotic movement of water out of their cytoplasm, and both work by increasing the internal osmolarity of the cell. In the first, organic compounds, termed "compatible solutes," are accumulated in the cytoplasm; this strategy has been found in many halophilic bacteria and also in some archaea, yeasts, algae, and fungi (Galinski, 1995). Compatible solutes are neutral or zwitterionic and include amino acids, sugars, polyols, betaines, and ectoines, as well as derivatives of some of these compounds; they can be synthesized de novo or taken up from the environment (Galinski, 1995; Grant, 2004). The second adaptation involves the selective import of K^+ ions into the cytoplasm, which can reach internal concentrations of 5 M. This adaptation is restricted to the moderately halophilic bacterial order *Halanaerobiales*, the haloarchaeal family *Halobacteriaceae*, and the extremely halophilic bacterium *Salinibacter ruber* (Oren, 2002). Most proteins of haloarchaea and also of *Salinibacter* contain a large excess of acidic amino acids (glutamate and aspartate) and a low content of basic amino acids (lysine and arginine; Lanyi, 1974; Oren, 2002); these features are thought to represent a specific adaptation to high levels of salt (Mevarech et al., 2000; Oren, 2002). In contrast, the action of compatible solutes is much less specific, with little or no adjustment of intracellular macromolecules required, which is in line with the observation that these compounds act as general stress protectants against heating, freezing, and drying (see Oren, 2002, and references therein).

Conclusions

Halophilic organisms occur in all major groups on the tree of life (see Oren, 2007) and even halophilic viral representatives are known. Halophilic microorganisms in particular

may be found on earth in almost every hypersaline environment – tropical to polar, terrestrial to submarine, acidic to alkaline, or aerobic to anaerobic (Javor, 1989). Initially a little-studied group of microorganisms, halophilic bacteria and archaea have proven to be of interest for life sciences and earth sciences as well; their investigation has resulted in major insights for molecular biology, genomics, biogeochemistry, and – most recently – astrobiology.

HAPTOPHYTES

Haptophytes (Haptophyta, Prymnesiophyta) are unicellular chlorophyll a and c containing algae with complex plastids derived from secondary endosymbiosis (“red lineage”) (see entry “*Symbiosis*”). They occur principally as solitary free-living motile cells that possess two smooth flagella, unequal in length in the Pavlovophyceae and more or less equal in the Prymnesiophyceae. Haptophytes inhabit littoral, coastal, and oceanic waters and are important primary producers in many aquatic environments. Within the haptophytes, the so-called coccolithophores (coccolithophorids) evolved the ability to control the intracellular calcification onto organic plates and the assembly of the mature calcium carbonate (calcite) scales (coccoliths) at the cell surface. These forms have been significantly contributing to the deposition of calcium carbonate in marine waters since the Mesozoic, today accounting for about a third of the total marine CaCO₃ production. In modern and ancient sediments, haptophyte-derived organic matter contributions can be specified by distinctive lipid biomarkers (alkenones), whose unsaturation patterns also provide a paleo-thermometer for past surface water temperatures (see entry “*Biomarkers (Molecular Fossils)*”). For further details, please see entry “*Algae (Eukaryotic)*.”

Definition

Histology is the biological science concerned with the minute or microscopic structures of cells, tissues, and organs of animals, plants, and fungi, in relation to their function, and any organismic constructions produced by living individuals or symbiotic assemblies of living organisms.

Biopsy is the sample of an organism or part of a tissue that is processed for histological investigations.

Fixation serves the inhibition of all vital processes by special chemicals that also preserve and prepare organic matter for further histological or morphological investigations.

Mineralization is the process by which organic components of organisms are impregnated or replaced by inorganic material and converted to mineral matter.

Staining is the chemical reaction of particular laboratory chemicals (stains and dyes) with tissue components and materials of the samples.

Introduction

The term histology was coined by C. Mayer in 1819 as a part of the scientific discipline comparative anatomy (Mayer, 1819). Histological investigations, concerned with the minute structures of cells, cell organelles, intra- and extracellular fiber arrangements, and tissue components and organs in relation to their function, are usually done by light microscopy. Since the invention of the microscope by Leeuwenhoek in 1668 (Palm and Snelders, 1983), the early histological technology (Gerlach, 1998) has experienced major improvement by the refinement of microscopes (Bozzola and Russell, 1999) and new methods of tissue preservation, sectioning devices, stains, and staining methods. Histochemical methods now permit to identify and localize intracellular components and enzymes within distinct and isolated samples (e.g., Bancroft and Gamble, 2007; Böck, 1989; Horobin and Kiernan, 2002; Mulisch and Welsch, 2010). Therefore, the studied structures, tissues, complete organisms, or any organismic compound have to be preserved from enzymatic decay, and then cut into sections of just a few microns thickness. The histological sections can vary between ultra thin sections (40–80 nm), semi thin sections (0.1–3.0 µm), thin sections (3–20 µm), and thick sections (more than 20 µm). While ultra thin sections could be investigated only by transmission or scanning electron microscopy (TEM), the others can be investigated with any light microscope. Afterward, these sections are

Introduction

The term histology was coined by C. Mayer in 1819 as a part of the scientific discipline comparative anatomy (Mayer, 1819). Histological investigations, concerned with the minute structures of cells, cell organelles, intra- and extracellular fiber arrangements, and tissue components and organs in relation to their function, are usually done by light microscopy. Since the invention of the microscope by Leeuwenhoek in 1668 (Palm and Snelders, 1983), the early histological technology (Gerlach, 1998) has experienced major improvement by the refinement of microscopes (Bozzola and Russell, 1999) and new methods of tissue preservation, sectioning devices, stains, and staining methods. Histochemical methods now permit to identify and localize intracellular components and enzymes within distinct and isolated samples (e.g., Bancroft and Gamble, 2007; Böck, 1989; Horobin and Kiernan, 2002; Mulisch and Welsch, 2010). Therefore, the studied structures, tissues, complete organisms, or any organismic compound have to be preserved from enzymatic decay, and then cut into sections of just a few microns thickness. The histological sections can vary between ultra thin sections (40–80 nm), semi thin sections (0.1–3.0 µm), thin sections (3–20 µm), and thick sections (more than 20 µm). While ultra thin sections could be investigated only by transmission or scanning electron microscopy (TEM), the others can be investigated with any light microscope. Afterward, these sections are

processed by various histochemical and biophysical techniques according to the aim of the study.

Geobiological samples usually do not consist of organic soft material, alone, like the above mentioned biological materials, but they are often composites of hard inorganic and mineralized organic material, with nearly all biological components converted to inorganic matter. Some geobiological samples are compositions of both, organic and inorganic materials, such as bio films growing on hard substrates, or sessile organisms that adhere to hard substrates like corals, sponges, lichens, or fungi. These samples therefore can seldom be histologically processed like biological material via paraffin embedding and sectioning with traditional microtomes. Special procedures and mechanical devices (like saw microtomes, annular saws or cutting/grindings systems) are necessary to produce sections of geobiological samples (e.g., Hoffmann et al., 2003). By means of special polishing machines, like the ultramill or lapping machines, sections or slices of these sections can be studied by distinct microscopical methods, for example under fluorescent light, X-ray-mappings and topographic element analyses (Janssens et al., 2000) can identify the outline of the biological compounds and their environment, and they may also serve as a biomarker; harsh biochemical treatment can isolate the organic from the inorganic components, but often destroy the original context. Histological analyses may provide tools to identify the biological components even if their former structural context has decayed (Wrede et al., 2008), or help to analyze particular processes or compositions (Neuweiler et al., 2007). Principally these results must be “calibrated” by means of histological investigations of recent tissues in order to understand organ structure and its function (Young and Heath, 2000).

This entry reviews the state of the histological methods and offers the modifications necessary to topographically investigate geobiological samples. *For clarity, this latter information is given in italics.*

Methods

Different from biochemical investigations in the broadest sense, histological analyses are concerned with samples, where the structures and their topographical context are preserved or known before biopsies are taken and only in a controlled way modified by procedures according to the specific aim of the study.

For histological processing of tissues or any other organic compounds, all vital functions have to be stopped by fixation, in order to preserve a distinct structure within or more often isolated from its natural environment. *In geobiology this process often is “history,” but must be known to understand the given results of further analyses.* Usually, the biological samples are embedded into a special medium which provides particular mechanical properties that allow sectioning in the appropriate thickness. The sections are then placed on glass slides or cover

slips, afterwards stained by special chemicals and dyes that have affinities to particular tissues or histological structures. The staining allows the differentiation of cell structures, various types of cell surface and skeleton assemblies, filaments or fibrillar components (e.g., collagenous fibers, elastic fibers, or reticular fibers), tissues, and even complete organs or pathological and genetic modifications of the various structures. Under the microscope the results can be observed and – most often after a thorough comparison to reference samples – evaluated and interpreted.

In geobiology, the selective staining of minerals prevails, although protein staining has been successful in various studies. The major problem in geobiology is that mineralized samples are too hard for conventional section procedures and therefore special preparation methods are necessary (see also below, paragraph “Embedding”). Accordingly, often only the surface of sectioned samples is accessible to the staining which limits the differentiations of components. Structural analyses of biological compounds have to refer to similar structures or organs histologically known from recent specimen. Therefore, histology in geobiology has to refer to a biological histology (Robenek, 1995). Specialized methods are available which either demineralize the sample for showing the biological contents or dissolve the organic leftovers to investigate their “casts” in the inorganic surroundings. Often the resulting histologically processed specimens can be biophysically investigated, and topographic X-ray element mappings (Janssens et al., 2000) are often the method of choice to serve as biomarkers.

Fixation and infiltration

The process of fixation and infiltration of biological specimens is most crucial for the results and aims to stop any autolytic and bacterial decomposition. The most commonly used fixative is formalin; however, other fixatives (e.g., Bouin, Carnoy, Paraformaldehyde, potassium dichromate, chromic acid, or mercury-fixation) are necessary depending on the planned subsequent protocol. The choice of the fixative determines the results, since every fixative has assets and drawbacks for the preservation of particular histological structures and especially the binding sites for differential staining, e.g., in immunohistology. For biophysical analyses, the metal-free fixatives and also metal-free pre- and post-processing protocols are essential.

The fixation process, which is a chemical reaction, has to be controlled and stopped after a particular time that depends on type and size of the tissue, but also on environmental factors like temperature and air pressure. Afterwards the fixative must be removed following a special protocol, which takes care not to destroy structural characteristics (Böck, 1989).

Prior to embedding, the sample has to be slowly transferred to the final substance via several intermediate steps mixable with the respective embedding medium, e.g.,

for the paraffin/wax embedding dehydrants (ethanol, isopropanol, and methanol) and clearants (xylene, toluene, and xylene-replacing clearants).

In case of aerated tissues, it may be necessary to perfuse the sample with a prefix and process fixation and embedding continuously in a vacuum with fluid movement for a proper impregnation of all layers of the specimen.

In geobiology, fixation and conservation also plays a crucial role, since these chemical processes have to be balanced between the necessities for the mineralized and organic components of a geobiological sample (biofilms or water containing fossils; e.g., Desrochers et al., 2007). Every fixative generates chemical reactions, which sometimes may degrade or destroy either the organic or the mineralized components. Accordingly, empirical studies have to be performed before crucial samples are processed in order to ascertain whether the fixative may cause any problems for either the soft or hard tissues of a particular type of samples.

Embedding

Embedding of histological material is performed in order to provide a mechanical stable and hard entity, which can be sectioned to various coherent thin sections. The sections should enable a spatial reconstruction of the original sample after differentiating analyses. The composition of the specimen and the histological program are decisive for the embedding methods of choice. The most common material for tissue embedding is paraffin (wax-embedding), also embedding in celloidin and resin. If the tissues under study are more or less soft (which means without any calcareous or other mineralized structures), the paraffin embedding is the best choice. Celloidin embedding takes much time and is useful for very sophisticated questions (e.g., embedding of complete brains or very large organs). Plastic embeddings are the best choice if the biopsies contain mineralized structures, such as calcium carbonate, calcium phosphate, and silicate, or if organismic components adhere to rocks or other hard substrates, like for example biofilms.

Therefore, these latter embedding methods lend themselves for geobiological samples, which then can be processed like biological material. For resin embedding (Howat et al., 2007) one can choose between epoxy-embedding, methyl-methacrylate-embedding, or glycol-methacrylate-embedding. Various products are commercially available (Obenauf et al., 2007), all of them have well-documented assets and drawbacks. The most drawbacks of plastic embeddings can be seen in their high costs of time and money. On the other hand, resin embedded samples can be sectioned, sawed, milled, or polished by use of various microtomes, saws, milling, or polishing machines.

Sectioning

Whole mount samples can only be investigated from their outer surface. Analyses inside the samples need dissection

with preferably minor destruction of the structural context. In general, penetration of staining chemicals is enhanced afterwards, and microscopic and biophysical inspection is improved as the spatial resolution corresponds to the thickness of the section. Several problems may arise from inappropriate section procedures:

- The samples may be too brittle and break. This effect is reduced by pre-treatment procedures like decalcification or demineralization, also choosing another type of embedding medium may help possibly combined with different section techniques, e.g., a vibrating knife or sample cooling by a special refrigerant device.
- The sections are heavily distorted. A proper selection of the microtome, cutting angle, and cutting velocity may improve the result. The sections may stretch, for example, after floating on a warm water bath about 10°C below the melting point of the embedding wax.
- The requested thickness requires different blades, which cannot be used “universally,” even if section series of varying thickness are necessary for the protocol. For example, thick sections need a hard metal blade, while semithin- and ultrathin sections can be produced only by means of glass or diamond knives.

Biological samples, which are embedded in paraffin or resin, can generally be sectioned by a special device, a microtome. Some microtomes are equipped with a motor-driven support, both for controlling the section thickness as well as the force of the blade. Several types of microtomes are available, each optimized for variably embedded samples: Paraffin embedded samples can be sectioned by sled microtomes or rotary microtomes equipped with metal knives. Resin embedded samples need microtomes which have a special retraction mechanism, to avoid mechanical damage of the knife and the sample. The blades are either manufactured of especially hardened steel for sections between 5 and 30 µm, for semi thin sections (2–5 µm) and ultra thin sections (about 40–100 nm) glass or diamond knives must be used.

Hard materials, like mineralized geobiological probes, cannot be sectioned by conventional microtomes unless the samples have been pre-treated: decalcification or demineralization by different chemicals. While these procedures may cause uncontrolled damage, when applied to the unsectioned samples, preferably control material should be preserved to evaluate the original structural context. Therefore, careful special section devices like diamond milling, saw microtomes, annular saws, or section/grinding-systems especially optimized for this purpose should be applied. About 30 µm thick sections of rather large samples can be achieved by these methods. The sections or grinded pieces can then be further processed, and also partly preserved for subsequent evaluation.

Another method, available since several years, is the laser microtome which may contact free isolate minute samples out of the otherwise untreated entity. The samples must neither be pre-treated nor embedded. Section thickness ranges between 10 and 100 µm. Special

devices allow even for the isolation of minute tissue pieces like a single cellular nucleus.

A satisfying section quality requires a long time of experience especially to decide for the most appropriate procedure. While continuously new embedding products are commercialized, only little has changed concerning the basic techniques of standard microtomy, which is taught as a component part of the education of laboratory and technical assistants.

Mounting

For further histological processing, the sections must be mounted, most often on glass slides or on grids coated with a special synthetic film.

The major difficulty is the choice of the best possible sticking procedures in order to prevent both, a floating resp. a loss of the sections during the staining protocol and undesired background staining by the glue. While before often unreliable “home-made” coating procedures, e.g., by chromic sulphate or polylysine, were used, now various types of pretreated glass slides are commercially available, they have been optimized for selected histological procedures. Thick sections, e.g., sections that are produced by saw microtomes or cutting/grinding-systems, have to be glued to object slides by special sticking resins that, e.g., harden with ultraviolet light; in this aspect, histological sample preparation is quite similar to the preparation of geological thin ground-sections.

Biophysical analyses of geobiological samples requires mounting according to the planned technique (see list of Handbooks of the suppliers). In, for example, X-ray investigations (micro fluorescence analyses), the mounting must be free of auto fluorescence; the sometimes long lasting measuring intervals need a stable non-vibrating mechanical stability.

Staining

Multiple histological staining methods allow identifying cellular structures, tissue components, and organ systems, also enzymatic processes and involved macromolecules. It is even possible to clearly differentiate between organic and inorganic material as well as decaying from living material by selective marking of minerals and molecules.

Stainings can be performed by use of natural stains and dyes or by chemicals often designed for certain projects. New fields of histological analyses have been launched by immunohistochemical stainings combined with fluorescent markers which are very selectively binding to particular proteins. Differential and double stainings, also section series with alternatively stained sections, have revealed important insight into basic cellular processes, information processing, and also pathological resp. genetic changes. The standard protocols are well documented including their modifications for the application to tissues of various origins.

For any staining it is necessary that the structures that should be stained are free of any embedding media. This means that for standard-histology the paraffin has to be removed by special procedures so that the staining chemicals can react with the tissues. If samples are embedded in resins, this process is more crucial and difficult; several resins cannot be removed and accordingly only the surface of the section provides reactive structures for staining.

The staining of cellular structures and tissues is based on chemical affinities of the stains with particular tissues resp. tissue components. In many cases, a particular pretreatment is necessary for adequate results. Pretreatments may be, for example, mordants, which modify the stain so that it reacts with the tissue or modifies the tissues so that the stain can react with the tissue. In some cases mordants generate a reaction that transformed the water soluble stain into a water- and alcohol-stable lacquer. This chemical reaction can, for example, be induced by metal ions like tungsten or molybdenum or by alkali ions like lithium, sodium, or barium (Böck, 1989; Burck, 1988).

Stainings are usually composed of three steps: in the first step cellular structures like nuclei, etc., are stained. In the second step cell plasma and some extracellular structures are stained, and in the third step the surrounding matrix is stained.

As a result of the staining, the nuclei, cells, various fibers, and other structures or chemical components in a tissue have particular colors that allow differentiation and several diagnostics. Some stainings also provide particular optical characteristics to tissues; they may for example provide polarizing effects to the tissue. Other procedures provide fluorescence-effects or particular ultra-violet-effects of the polished surface and allow further investigations (Figures 1 and 2).

While traditional stainings induce a chemical reaction within tissues and may stain in an unselective way (Horobin and Kiernan, 2002), immunohistology (Polak and Noorden, 2003) selectively marks specific epitopes, proteins, and molecules bound to membrane or subcellular structures. Traditional and immunohistochemical analyses under the light microscope meet the limits of resolution at magnifications of about 1,200 $\times$; therefore, immunohistological methods have been upgraded for analyses under the TEM, either by pre-embedding or post-embedding staining protocols.

While traditional stainings are used for topographic and micro anatomical investigations, immunohistological stainings are used to understand the functional context of molecular processes and to allocate the regions in which these processes take place in an organism or in a tissue.

These refined immunohistological staining methods have also been applied to sections of geobiological samples. The analyses could demonstrate biological compounds, thus serving as biomarkers, and in some cases even disclose the genetic origin of the fossilized organisms.

Histology, Figure 1 Cross section of a human long bone under different microscopic optics (thin-ground section of a non-demineralized sample). (a) Under through light with minimal color saturation; (b) same illumination with maximum color saturation; (c) differential interference contrast (After Nomarski). Already without staining procedures characteristic structural details and varying densities can be identified. (a–c same magnification.)

Conclusion

Geobiology is defined as field of science which analyses the interaction of the environment with living matter. Mainly fossilized samples are investigated concerning their systematic relationship and – even more – the origin of this specific form of life. Research results can find their application not only in a better understanding of our life on earth, but also in exploring putative extraterrestrial biology. Another aspect is the transfer of basic sciences to various aspects of biomedical research like the synthesis or degradation of bones and teeth or the control of biogenic mineralization processes. All these research topics cannot be planned and performed or adequately evaluated without a thorough knowledge of the biological structures mainly based on the comparison of living and fossilized specimen. Histology delivers the methods to topographically analyze organisms, organs, tissues, and even molecules. Their modifications by environmental or biogenic processes can be recognized by the investigation of their complex interaction.

Perspectives

Histological investigations provide a huge field of research for biology and geobiology. Both fields have to be combined, since geobiological samples often can only be interpreted with reference to known biological samples. Some examples are histological sections of dinosaur bones or teeth that have to be compared to bones and teeth of recent organisms, others are the discoveries at special fossil-sites, like the Messel pit, the Burgess-Shale, the rocky Hunsrück region, etc., which may provide interesting information about fossilized microscopic structures. And even the investigation of recent samples like biofilms or coatings is of major relevance to understand their composition and emergence in order to discriminate between biogenic and abiotic origin.

Summary

Histology provides methods to topographically investigate the structure of cells, tissues, and organs down to the molecular level, especially in geobiology as reference to recognize, for example, the phylogenetic origin and age and also as a basis to analyze biological in comparison to bio geological turnover processes, which induce structural changes via environmental and climatic conditions.

HOT SPRINGS AND GEYSERS

Brian Jones¹, Robin W. Renaut²

¹University of Alberta, Edmonton, Alberta, Canada

²University of Saskatchewan, Saskatoon, SK, Canada

Definition

A *hot spring* is a discharge of hot (>35 – 40°C) water from a vent at the Earth's surface.

A *geyser* is a hot spring characterized by intermittent, turbulent discharges of boiling water and steam.

A *sublacustrine hot spring* is a hot spring that discharges from the floor of a lake.

Introduction

A hot spring is characterized by discharge of hot water from a vent. There is, however, no universally accepted definition of “hot” and the temperature for distinguishing a “warm spring” from a “hot spring” remains contentious (Pentecost et al., 2003). In general usage, a hot spring is one with vent water temperature between about 40°C and boiling point (Renaut and Jones, 2000). It must be remembered, however, that boiling temperature changes with altitude; thus, boiling in Yellowstone National Park occurs at $\sim 92^{\circ}\text{C}$, whereas in New Zealand geothermal areas, which lie closer to sea level, it is at $\sim 100^{\circ}\text{C}$.

The term “geyser” is derived from “Geysir,” located in southwest Iceland. First mentioned in historical records from 1294, the Icelandic word “geysir” means “gusher” or “one who rages.” Accordingly, a geyser is regarded as hot spring that is characterized by intermittent, turbulent discharges of boiling water and steam (Bryan, 2005, 2008).

Geysers and hot springs are end members of a continuous spectrum that includes “intermittent springs” that experience periodic overflows but never erupt, and “pulsating springs,” “perpetual spouters,” or “ebullient springs” that are characterized by continual eruptions. Some hot springs discharge on the floors of lakes and in caves.

Distribution

Hot springs and geysers are found on every continent except mainland Antarctica (Waring, 1965). Many hot springs and geysers, known from historical records, have ceased activity because of natural and anthropogenically induced changes to their plumbing systems. Yellowstone National Park, USA., El Tatio located high in the Andes of northern Chile, the Taupo Volcanic Zone on the North Island of New Zealand, Kronotski National Park in Kamchatka in eastern Russia, and Iceland are the largest known geothermal fields with numerous hot springs and geysers. Bryan (2008), for example, estimated that more than 50% (~ 500) of known geysers are located in Yellowstone National Park, with another 385 in the other four major geothermal areas. Low-enthalpy hot springs that discharge at maximum temperatures of about 35 – 60°C are much more common.

The plumbing system

The hot water discharged by a hot spring or geyser is the final, surface expression of a complex system that involves water, a heat source, and an intricate underground plumbing system. The water is derived from meteoric waters that have seeped deep into the Earth's crust, supplemented in some regions by connate, magmatic, or metamorphic waters. Irrespective of its origin, some spring or geyser water may come from depths of ~ 4 km where it has been magmatically heated to temperatures of $>225^{\circ}\text{C}$. In other settings, however, meteoric waters may only penetrate to shallow depths before being expelled from a low-enthalpy spring vent. The plumbing system of a hot spring is unrestricted and allows continuous movement of water to the surface. In contrast, a geyser has a restriction within its plumbing system, commonly a sinter caprock that precludes continuous vertical flow. The configurations of these plumbing systems remain unknown because of the difficulties in accessing them. Nevertheless, schematic depictions of vast underground, water-filled chambers are probably incorrect. Instead, it seems that the plumbing systems are formed of complex networks of faults, fractures, small cavities, and strata with variable permeability. Geysers are less common than hot springs because of the special plumbing system requirements.

Water trapped below a restriction in a geyser plumbing system will be heated by steam that is moving upwards from deeper parts of the system. The reservoir will then empty as the trapped superheated water is violently discharged. Such an eruption will continue until the reservoir is emptied. The magnitude, frequency, and duration of the eruption depend on reservoir size, the rate of heat transfer, and the rate at which water refills the system once emptied by the eruption. By necessity, therefore, geysers can only exist if the bedrock can withstand the pressures created by the steam and if the bedrock is permeable enough to allow rapid reservoir replenishment.

HYDROGEN

Tori M. Hoehler
 NASA-Ames Research Center, Moffett Field, CA, USA

Synonyms

Dihydrogen; H₂

Definition

A diatomic molecule consisting of two atoms of hydrogen or its heavier isotopes.

Introduction

Hydrogen, the most abundant element in the universe by mass and number, exists on Earth principally in combination with oxygen (in H₂O) or carbon (in hydrocarbon and

organic compounds). The diatomic form, H₂ – although present in only trace abundance in the modern oceans and atmosphere – has played a central and evolving role in prebiotic and origin of life chemistry, in linking geochemical and biological cycles, and in shaping the structure, function, and interaction of microbial populations.

Geochemistry of H₂

Geosphere

H₂ is produced by the interaction of water and rocks through a variety of mechanisms (see review in Hoehler, 2005). Among processes that occur in widespread crustal rocks, perhaps the best known and most quantitatively important involves the reduction of water to H₂ by the ferrous iron components of rocks, which can be generalized as

with (FeO)_{rock} representing the ferrous iron component of igneous rock and (Fe₂O₃)_{rock} representing the ferric iron component of alteration minerals (e.g., magnetite). The capacity for H₂ generation via this mechanism is greatest in minerals with high ferrous iron contents, such as the ultramafic minerals olivine and pyroxene, where the process is called serpentinization. Basalts, with a lower ferrous iron content, have a smaller capacity to produce H₂, and granites (where ferrous iron-bearing phases are typically present as minor components) smaller still. The rates of hydrogen generation by water–rock reaction depend significantly on both temperature and the exposure of fresh surface area to water.

H₂ may also be generated via the radiolytic cleavage of water by α, β, or γ radiation produced during decay of isotopes in the host rocks (Spinks and Woods, 1964). Although oxidative species generated simultaneously during the process have potential to recombine with the hydrogen, radiolysis is nonetheless believed responsible for elevated H₂ concentrations (up to millimolar levels) in fluid emanations from a number of continental rock units. This mechanism is generally most important for granites, in which the content of the principal radiogenic elements U, Th, and K is generally highest among major crustal rock types.

Fracturing of silicate rocks may also serve to liberate H₂ that is formed either in solid-state reactions involving trace water impurities in the mineral lattice (Freund et al., 2002) or by direct reduction of water at the fractured surface (Kita et al., 1982).

Among these processes, serpentinization offers the greatest potential capacity for H₂ generation (per unit volume of rock), by orders of magnitude. However, multiple factors – including mineral composition, fluid flow and chemistry, temperature regime, and mechanical processing – ultimately determine which mode of lithogenic H₂ production may prevail in a given environment.

Atmosphere

H₂ is a trace component of the modern atmosphere, with an abundance of about 0.5 ppm (Levine, 1985) and a residence time of less than 1 year (Atkinson et al., 1979), but likely higher levels in the early atmosphere would have had important geochemical and biological implications. Atmospheric H₂ abundance reflects a balance of sources and sinks. Major source terms (excluding anthropogenic sources) include geological efflux (e.g., volcanic and hydrothermal vent emissions) and biological production. Sinks include oxidative atmospheric reactions, biological consumption, and escape to space. The low abundance of H₂ in the modern atmosphere reflects the dominance of oxidative reactions and biological consumption. The early, prebiotic Earth largely lacked such sinks and had a geological source term that was expectedly larger as a result of higher rates of geothermal emanation and a potentially more reducing character in the early mantle and crust (leading to higher H₂ concentrations in geothermal emanations). Estimates of atmospheric H₂ abundance at this time depend principally on theories regarding the oxidation state of the early mantle and crust, and consideration of the factors constraining H₂ escape to space. Even at the low end, these estimates generally predict atmospheric H₂ abundance of hundreds to thousands of parts per million, 3–4 orders of magnitude higher than in the present day.

H₂ itself is considered photochemically inert in the lower atmosphere (Levine, 1985), but it participates in a variety of reactions involving the radical products of photolysis. By serving as a sink for the oxidizing OH radical (Atkinson et al., 1979), and influencing the abundance of the atmospheric reductants H, HCO, and H₂CO (Canuto et al., 1983), H₂ directly affects the oxidation state of the atmosphere. As such, its relative abundance in the early atmosphere may have significantly affected redox speciation in the volatile nitrogen, carbon, and sulfur systems. In turn, this balance (e.g., the CH₄/CO₂ ratio, in the carbon system) affects the atmospheric radiation budget (through differing efficiencies of IR absorption), the potential for formation of photochemical hazes (Sagan and Chyba, 1997), and the formation and stability of simple organics in atmospheric chemical processes.

Above and beyond its role in buffering the oxidation state of the atmosphere through chemical interactions, escape of hydrogen to space can contribute to the irreversible oxidation of the planet, by carrying electrons out of the system (Walker, 1977). This process occurs at low rates in the modern, oxidized atmosphere, where the low abundance of H₂ results in low escape rates. However, H₂ escape from an early atmosphere containing orders of magnitude higher H₂ concentrations may have contributed substantially to the overall oxidation of the planet.

H₂ in prebiotic and origin of life chemistry

Prebiotic chemistry

The emergence of life must depend significantly on development of an inventory of abiotically generated compounds

that can serve as building blocks for biochemistry. Two of the most potentially important endogenous sources for such compounds – synthesis in hydrothermal vent settings and in atmospheric chemical processes – are known or inferred to depend strongly on H₂ for the yield and nature of compounds formed. In vent settings, H₂ from water–rock reactions is implicated as the reductant in Fischer–Tropsch type synthesis of methane, higher hydrocarbons, and simple organic acids, and is predicted to support the synthesis of amino acids and other prebiotic compounds. Miller–Urey type spark discharge experiments that simulate atmospheric chemical processes have a similar dependence that is demonstrated experimentally. For example, the yield of amino acids from simpler precursors in such experiments depends directly on the abundance of H₂, regardless of whether reduced or neutral starting materials (i.e., CH₄/NH₃ (Miller and Urey, 1959), or CO₂/N₂ (Schlesinger and Miller, 1983)) are used. Given its significance in prebiotic synthesis and atmospheric redox and photochemistry on the early Earth (see above), H₂ likely played an important overall role in establishing the environmental and chemical context from which life emerged.

Origin of life

Although the specific chemistry leading to the origin of life is not known, H₂ is proposed in some scenarios to have been a key component of the earliest metabolism (Wächtershauser, 1993). The oxidation of H₂ serves a potentially important dual purpose with respect to such metabolism, in yielding both reducing power and H⁺. Reducing power is necessary for generating organic biomolecules when the carbon source is CO₂. The establishment of H⁺ gradients (specifically, across membranes) can be used to store energy for subsequent coupling to biochemistry. Such dual-purpose chemistry underpins the metabolism of a wide range of modern organisms, including those thought to represent Earth's earliest life. The widespread availability of H₂ in geothermal emanations (e.g., Zobell, 1947; Elderfield and Schulz, 1996) and, presumably, in the prebiotic oceans and atmosphere would have made it a ubiquitous and reliable substrate on which to base the first metabolic chemistry.

H₂ and biology

The reversible oxidation of molecular hydrogen, $\text{H}_2 \rightleftharpoons \text{H}^+ + 2\text{e}^-$, is among the most widely utilized reactions in microbial metabolism. Hydrogenases, the enzymes which catalyze this transformation, are present in all three phylogenetic domains of life (Fenchel and Finlay, 1995; Vignais et al., 2001; Schwarz and Friedrich, 2003). They are particularly widely represented in the Bacteria and Archaea, including the most deeply branching and least derived lineages (Vignais et al., 2001; Schwarz and Friedrich, 2003), suggesting that, exclusive of a possible role in origin of life chemistry, H₂ metabolism has been an important contributor to biochemistry since the very early stages of evolution.

Since its emergence in metabolism, H_2 -based redox chemistry has come to be associated with an extremely broad range of microbial metabolic strategies, including oxygenic and anoxygenic phototrophy, anaerobic chemolitho- and chemoheterotrophy, and aerobic chemolithotrophy (Schwarz and Friedrich, 2003). H_2/H^+ can serve as electron donor, acceptor, or both, in these processes. This broad metabolic utility and versatility casts H_2 in a highly central role in the ecology of microbial communities, and in the geochemistry they mediate.

Lithotrophic communities

Organisms capable of H_2 metabolism can potentially be supported directly by geochemical production of H_2 (by, e.g., water–rock reaction or radiolysis). As such, they have potential to exist independently of energy input from light or the direct products of photosynthesis, oxygen, and organic matter. Such communities are therefore frequently envisioned as important contributors to Earth's earliest biosphere, to the rock-hosted subsurface biosphere, and, potentially, to subsurface life on other worlds. H_2 -based, photosynthesis-independent communities have been documented or inferred for a range of systems and H_2 -producing mechanisms, including vent fluids sourced in serpentinizing systems, basalt-hosted aquifers, and continental groundwaters bearing a signal of radiolytic H_2 production.

Heterotrophic communities

Systems driven by anaerobic decomposition of organic matter typically host a great diversity of H_2 -cycling organisms. Under anaerobic conditions, the complete degradation of complex organics cannot be accomplished by a single organism. Instead, the overall process is mediated, in a series of individual steps, by communities of microorganisms having different metabolic capabilities (Schink, 1988). The individual steps are linked through the transfer of electrons from one group of microbes to another, with H_2 serving as one of the most commonly employed molecular carriers of electrons. The pool of H_2 in such systems is typically characterized by low concentrations (sub-nanomolar to micromolar) and rapid turnover, with resultant residence times frequently in the range of seconds (Hoehler et al., 2002). Combined with a strong influence on the thermodynamics of reactions that produce or consume it (resulting from its typically high stoichiometric coefficient in such reactions), this effect casts H_2 as a key regulator of degradation pathways, community structure, and carbon and energy flow in such environments. Specifically, fluctuations in H_2 concentration are documented, in a process known as “interspecies H_2 transfer,” to affect the H_2 -cycling reactions by inhibition or stimulation, alteration of products, or even reversal (see review in Hoehler, 2005).

H_2 thus occupies a central role in anoxic ecosystems. Anoxia prevailed globally prior to about 2.4 billion years ago and continues to prevail in most organic-bearing

aqueous environments (including ocean, lake, and wet-land sediments and animal digestive tracts). In the past and present, such systems represent a major control on the redox chemistry of the oceans and atmosphere, and the ultimate biological filter on material passing into the rock record.

Phototrophic communities

Most of the known photosynthetic microorganisms, representing both anoxygenic and oxygenic photosynthesis, possess a capability to engage in H_2 metabolism (Schwarz and Friedrich, 2003; Vignais et al., 1985). Most anoxygenic photosynthesizers, including representatives of the purple sulfur, purple non-sulfur, green sulfur, and green non-sulfur bacteria, can utilize H_2 as an electron donor for photosynthetic carbon fixation, and several are also capable of utilizing H_2 as an electron donor for the chemical reduction of inorganic oxidants. Some representatives of the cyanobacteria (oxygenic photosynthesizers) are similarly capable when operating in an anoxygenic photosynthetic mode of metabolism. H_2 is produced obligately during the conduct of nitrogen fixation and can also be photo-produced by the nitrogenase enzyme complex independently of nitrogen fixation. These capabilities, which occur widely among the cyanobacteria and anoxygenic photosynthesizers, are among the principal mechanisms being explored for biological production of H_2 as an alternative energy source. H_2 is also generated as a product of fermentation, a capability demonstrated in some cyanobacteria and purple sulfur bacteria. The fermentative mode of H_2 production appears to dominate the H_2 cycle in a variety of cyanobacterial “mats,” resulting in significant fluxes of H_2 out of the system (Hoehler et al., 2001; Hoehler et al., 2002). During the 1–2 billion years of Earth's history in which cyanobacterial mats dominated biological productivity on Earth, such fluxes may have contributed significantly to atmospheric H_2 levels and, by enhanced rates of H_2 escape to space, the overall oxidation of the planet.

Eukarya

Although not as widespread as in the *Bacteria* and *Archaea*, H_2 metabolism is also found in the *Eukarya*. In a variety of deep-branching anaerobic Eukaryotes, metabolism is tied to, or dependent on, an H_2 -based symbiosis with Bacterial or Archaeal partners (see review in Fenchel and Finlay, 1995). The driver of most of these symbioses is an H_2 -generating organelle, the hydrogenosome, which appears in some cases to be derived from a mitochondrion. These hydrogenosomes carry out fermentation, rather than oxidative phosphorylation, of pyruvate – and thereby produce H_2 . Microbial symbionts (which may include methanogens, sulfate reducers, and (in one case) photosynthetic purple non-sulfur bacteria) increase the energetic yield of this fermentation by consuming the end product H_2 . The symbiosis significantly enhances the growth of the host, and is, in some cases, so evolved that methanogen symbionts have lost their cell walls, and exhibit synchronization of cell

division with the host. Among photosynthetic Eukarya, green algae exhibit an active H_2 metabolism, and are considered a promising potential source of “biohydrogen” for alternative energy systems.

Summary

Hydrogen has played an important role in Earth's geochemistry and biology since the earliest stages of the planet's history. H_2 is produced by a variety of geochemical processes and is postulated to have been a significant component of the early, prebiotic atmosphere, where it had direct or indirect effects on atmospheric redox chemistry and radiation budget, and contributed to planetary oxidation by escape to space. Prebiotic and origin of life chemistry may have significantly involved H_2 , and its prominent use among deeply branching organisms in the tree of life reflects, at very least, a key role in metabolism since the biosphere's early stages. In the modern biosphere, H_2 biochemistry is associated with a broad variety of metabolic strategies, in all three domains of life. Although it now represents a trace component of the oceans and atmosphere, the significance of H_2 for planetary chemistry persists through its central role in the microbial world.

Definition

“Black smokers” represent extreme hydrothermal activities that are commonly located in deep sea environments

division with the host. Among photosynthetic Eukarya, green algae exhibit an active H_2 metabolism, and are considered a promising potential source of “biohydrogen” for alternative energy systems.

Summary

Hydrogen has played an important role in Earth's geochemistry and biology since the earliest stages of the planet's history. H_2 is produced by a variety of geochemical processes and is postulated to have been a significant component of the early, prebiotic atmosphere, where it had direct or indirect effects on atmospheric redox chemistry and radiation budget, and contributed to planetary oxidation by escape to space. Prebiotic and origin of life chemistry may have significantly involved H_2 , and its prominent use among deeply branching organisms in the tree of life reflects, at very least, a key role in metabolism since the biosphere's early stages. In the modern biosphere, H_2 biochemistry is associated with a broad variety of metabolic strategies, in all three domains of life. Although it now represents a trace component of the oceans and atmosphere, the significance of H_2 for planetary chemistry persists through its central role in the microbial world.

Black and White Smoker communities; Volcanogenic massive sulfide deposits – VMS

Definition

“Black smokers” represent extreme hydrothermal activities that are commonly located in deep sea environments

related with mid-ocean ridges and/or oceanic crust fault systems. Hydrothermal vent systems result from hydrothermal circulation of fluids controlling the transfer of energy and various matter from the interior to the surface of the oceanic crust, respectively the sediment surface. This hydrothermal circulation is a fundamental geological process and has been permanently influencing the chemistry of the oceans, and in consequence, also the composition of the entire earth crust. Seafloor hydrothermal activity has a major impact on the chemistry and life processes of the oceans (Parson et al., 1995; Humphries et al., 1995; van Dover, 2000). This entry focuses on volcanogenic massive sulfide deposits (VMS) and not on sedimentary exhalative deposits (SEDEX) – however, the boundary between both environments is not very strict. Massive sulfide deposits, hydrothermally altered rocks, and special communities of organisms are an important record of this process. Ancient seafloor hydrothermal activity is recorded in massive sulfides from the 3.5 GY-old Pilbara region of Western Australia (Barley, 1992). The new findings of hydrothermal vents with microbialites from 1.43 GY-old Precambrian rocks in northern China (Li and Kusky, 2007) are also of great interest. Within the Phanerozoic, roughly 20 sites are known with fossil hydrothermal vent communities (Little et al., 1998).

Geobiological notes

Hydrothermal vents have become one of the most fascinating fields of research in marine sciences. The recognition of complex vent communities consisting of organisms dependent on chemolithotrophy and extreme conditions of very high temperature, pressure, and chemistry at the ocean ridges was a great discovery (Humphris et al., 1995). There are many reasons to believe that life originated at hydrothermal vent environments in the late Hadean. However, only few publications are dealing with the fossil record of hydrothermal environments connected with preserved organism communities.

There are about 20 known Phanerozoic VMS sites with preserved hydrothermal vent communities, ranging from the Silurian to the Eocene. Most of these sites are found in the Ural Mountains and on Cyprus, some of them in Ireland, California, Philippines, and New Caledonia. All occurrences are linked to remains of oceanic crust (ophiolites). The investigation of vent systems is still a challenge, because the sites are normally small and most of them were destroyed during subduction of oceanic crust.

The vent communities contain assemblages of inarticulate and rhynchonellid brachiopods, gastropods, bivalves, and also monoplacophorans (Little et al., 1998; Kiel and Little, 2006). Remains of worm tubes are very characteristic and may be related to alvinellid polychaetes and pogonophorid-vestimentiferan chemotrophic worms. Most of the fossil taxa of the vent sites are endemic. However, the diagenetic loss of the original shell material makes it very difficult to classify the worm tubes in a modern

taxonomic scheme. Surprisingly, no arthropods were found at the fossil sites, whereas arthropods are very common in modern vent environments. There is an ongoing discussion on the origin of the vent fauna. New groups of organisms may have immigrated from the ambient environment and adapted to the extreme conditions of the vent sites and vice versa, some of them have left this environment. The origin of the vent faunas is thoroughly discussed in Kiel and Little (2006) and Little and Vrijenhoek (2003). Kiel and Little (2006) suggested that the mollusk seep faunas (hydrothermal vents and cold seeps) have a significantly longer evolutionary history than normal marine mollusks and show a tight taxonomic relationship with deep-sea mollusk faunas. The oldest known Phanerozoic hydrothermal vent is of Silurian age (Little et al., 1998). The discovery of the Mesoproterozoic (1.43 GY) hydrothermal vents in northern China was of great importance due to very well-preserved filamentous microbial communities forming massive sulfidic microbialites (Li and Kusky, 2007).

Conclusion

Fossil hydrothermal vent systems are known since the early Archaean and represent important geobiological environments. These environments have a significant key role in biological evolutionary processes. However, only few (ca. 20) sites are known worldwide in the Phanerozoic with preserved vents faunas. The oldest known fossil hydrothermal vent system with a metazoan community is known from the Silurian of the Ural Mountains (Little et al., 1998). Many of the vent organisms probably have a significantly longer evolutionary history than normal marine taxa (Kiel and Little, 2006).

Marine hydrothermal environments are one of the most extreme environments on Earth, yet they support highly productive biological communities over a wide range of physical and chemical environments. The following review is a general discussion of the types of microorganisms found in these different environments preceded by brief descriptions on hydrothermal fluid generation, mineral deposit formation, and microbial metabolism.

Introduction

The discovery of deep-sea hydrothermal vents and the lush biological communities associated with them in the late 1970s ushered in a new era for marine biologists. Prior to this discovery, life in the deep-sea was thought to be dependent on the settling of detrital material from the productive, overlying surface waters. While this is true for much of the ocean basins, the level of production observed at these newly discovered vent sites was too great to be supported by these mechanisms alone. It soon became evident that life in these environments was supported by chemosynthetic primary production in which microorganisms harnessed the abundant geochemical energy available in the hydrothermal fluids. This challenged one of the basic ecological premises that all ecosystems on Earth were dependent on light energy and driven by photosynthetic primary production.

Since those initial revelations, research efforts have focused on assessing the microbial diversity and attempting to understand the intimate associations between microbial productivity, geology, and geochemistry in marine hydrothermal environments. This article is a general discussion of the trends that are beginning to emerge from these efforts. Included in the discussion are overviews of the geologic setting of marine hydrothermal systems, the generation of hydrothermal fluids from different geologic settings, and the types of structures formed.

For additional in-depth reviews, the Geophysical Monographs published by the American Geophysical Union (AGU) are valuable resources (Humphris et al.,

1995; German et al., 2004; Wilcock et al., 2004; Christie et al., 2006).

Geological setting

Most seafloor hydrothermal vent systems are associated with extensional tectonic activity and heated by magmatic heat as it is convected into the crust (Seyfried and Mottl, 1995). The most well-studied areas of hydrothermal circulation are along divergent plate boundaries where basaltic seafloor is made and mid-ocean ridges (MOR) arise (Figure 1). Hydrothermal circulation along MORs results from the active heating of seawater that percolates through newly formed basaltic crust. Hydrothermal venting is also commonly found along convergent plate margins where an oceanic plate is subducted beneath a continental plate forming island arcs and back-arc basins (Christie and Fisher, 2006). Vents along back-arc basins are actively heated in the same way as those along MOR, although the fluids tend to be more heterogeneous due to the variability in magma composition and additional inputs from the subducting plate (GAOM et al., 2006). A third location where seafloor hydrothermal systems can be found is at intraplate volcanic hot spots. Volcanic hot spot systems are not directly associated with tectonic plate margins, but are actively heated as plumes of molten magma push up through the mantle and crust (Seyfried and Mottl, 1995).

The recently discovered Lost City vent field more than 15 km off axis of the Mid-Atlantic Ridge (MAR) represents a new type of seafloor hydrothermal system as it appears to be at least partially heated by exothermic reactions between mantle derived peridotite and seawater (Kelley et al., 2001). These reactions have a dramatic impact on the composition of the hydrothermal fluids, which in turn affects the microbial community as discussed in the following sections. Although Lost City represents the first vent type of its kind discovered, similar systems are believed to exist along margins of slow- and ultraslow-spreading ridges where uplifting of ultramafic massifs are common.

Hydrothermal fluids

Seawater heated in contact with subsurface rocks dramatically alters the chemical composition of the end member fluids. The degree of alteration is influenced by several factors including the initial composition of the seawater, the type and structure of the host rock, the presence of sediment overlaying the host rock, and the type, depth, and size of the heat source (reviewed in Tivey, 2007). Understanding these interactions and how they affect the composition of hydrothermal fluids is important as the fluids set the physiological parameters and provide the metabolic menu for colonizing microbes. For comparison, representative compositions of hydrothermal fluids from different settings are presented in Table 1.

1995; German et al., 2004; Wilcock et al., 2004; Christie et al., 2006).

Geological setting

Most seafloor hydrothermal vent systems are associated with extensional tectonic activity and heated by magmatic heat as it is convected into the crust (Seyfried and Mottl, 1995). The most well-studied areas of hydrothermal circulation are along divergent plate boundaries where basaltic seafloor is made and mid-ocean ridges (MOR) arise (Figure 1). Hydrothermal circulation along MORs results from the active heating of seawater that percolates through newly formed basaltic crust. Hydrothermal venting is also commonly found along convergent plate margins where an oceanic plate is subducted beneath a continental plate forming island arcs and back-arc basins (Christie and Fisher, 2006). Vents along back-arc basins are actively heated in the same way as those along MOR, although the fluids tend to be more heterogeneous due to the variability in magma composition and additional inputs from the subducting plate (GAOM et al., 2006). A third location where seafloor hydrothermal systems can be found is at intraplate volcanic hot spots. Volcanic hot spot systems are not directly associated with tectonic plate margins, but are actively heated as plumes of molten magma push up through the mantle and crust (Seyfried and Mottl, 1995).

The recently discovered Lost City vent field more than 15 km off axis of the Mid-Atlantic Ridge (MAR) represents a new type of seafloor hydrothermal system as it appears to be at least partially heated by exothermic reactions between mantle derived peridotite and seawater (Kelley et al., 2001). These reactions have a dramatic impact on the composition of the hydrothermal fluids, which in turn affects the microbial community as discussed in the following sections. Although Lost City represents the first vent type of its kind discovered, similar systems are believed to exist along margins of slow- and ultraslow-spreading ridges where uplifting of ultramafic massifs are common.

Hydrothermal fluids

Seawater heated in contact with subsurface rocks dramatically alters the chemical composition of the end member fluids. The degree of alteration is influenced by several factors including the initial composition of the seawater, the type and structure of the host rock, the presence of sediment overlaying the host rock, and the type, depth, and size of the heat source (reviewed in Tivey, 2007). Understanding these interactions and how they affect the composition of hydrothermal fluids is important as the fluids set the physiological parameters and provide the metabolic menu for colonizing microbes. For comparison, representative compositions of hydrothermal fluids from different settings are presented in Table 1.

Basalt hosted hydrothermal fluids

Water–rock reactions begin as cold seawater infiltrates shallow basalt in the recharge zones (Figure 2). Initial low temperature reactions ($\leq 60^\circ\text{C}$) result in the removal of alkali metals from seawater and the oxidation of basaltic minerals (i.e., olivine and plagioclase), with the concomitant leaching of silica (Si), sulfur (S), and sometimes magnesium (Mg) from the minerals (reviewed in Alt, 1995). Magnesium is eventually completely removed from the fluids as Mg-rich clays precipitate at temperatures above 150°C . Anhydrite (CaSO_4) precipitation and seawater sulfate (SO_4^{2-}) reduction also occur in the recharge zone at temperatures above 150°C , resulting in the complete removal of SO_4^{2-} from the fluids. As the fluid continues through the crust, reactions with iron-bearing minerals such as olivine and pyroxene result in highly reducing fluids with elevated concentrations of hydrogen gas (H_2) (Tivey, 2007). Upon reaching the reaction zone where fluids are heated upward of 400°C , the fluid obtains its chemical signature by leaching S and metals (copper-Cu, iron-Fe, manganese-Mn, zinc-Zn) from the surrounding rocks (Alt, 1995). Phase separation

may also occur in the reaction zone if temperature and pressure are greater than 407°C and 298 bars, respectively (Von Damm, 1995). Phase separation can have a significant impact on the composition of end member fluids as volatiles such as hydrogen-sulfide (H_2S) tend to partition in the vapor phase while metals such as Fe become enriched in the liquid (brine) phase. Gases such as helium (He), methane (CH_4), and carbon dioxide (CO_2) may also be added to the hydrothermal fluids as volatiles from the underlying magma (Alt, 1995). In total, these reactions result in end member fluids that are acidic (pH 2.8–4.5), highly reduced, rich in H_2S and metals, and heated up to 400°C . The fluid is also extremely buoyant relative to seawater and is forced back to the seafloor through the discharge zone and may emerge as diffuse or focused flow depending on the degree of subsurface mixing during the ascent (Figure 2).

Other factors, such as differences in host rock and sediment cover, can contribute to the chemical composition of end member fluids. The impact that different host rocks have on fluid chemistry is best illustrated by the ultramafic hosted Rainbow vent field along the MAR

Hydrothermal Environments, Marine, Table 1 Representative chemical compositions of hydrothermal fluids from different geologic settings

Characteristic	Deep seawater	Mid-ocean ridge	Back-arc basin	Sediment hosted	Rainbow vent field	Lost City

Modified after Tivey (2007). *bdl* below detection limit

(Douville et al., 2002). Fluids from Rainbow vent field are lower in pH, have much higher Fe concentrations, are enriched in H₂ and CH₄, and are depleted in H₂S relative to fluids from most MOR systems (reviewed in McCollom, 2007). These differences in composition are related to the same serpentinization reactions that fuel the Lost City vent field (see below) although the heat sources differ. Sediments overlying the host rock can also affect the composition of end member fluids (German and Von Damm, 2004). In general, sediment-hosted systems generate fluids that are higher in pH (5.1–5.9) and lower in metal contents than those from unsedimented systems. Chemical differences largely depend on the amount and type of organic matter present in the sediments (Tivey, 2007).

Lost City hydrothermal fluids

Hydrothermal fluid generation at Lost City begins much in the same way as fluid generation at MOR systems, with the infiltration of seawater into rock. However, the rock is not basalt but rather mantle-derived peridotite which reacts with seawater to form serpentinite (Kelley et al., 2001). Serpentinization reactions result in the hydration of minerals such as olivine and produces large amounts of heat, H₂, and CH₄. This heat is believed to at least partially drive hydrothermal circulation at Lost City although other heat sources have been suggested (Kelley et al., 2001; Allen and Seyfried, 2004). Regardless of the heat source, the end member fluid chemistry is dramatically different than MOR vent systems and is indicative of seawater–rock reactions below 150°C. The most striking differences are the alkaline pH (≈10–11), the lower temperatures (up to 93°C), the elevated calcium (Ca) content, and the low concentrations of metals and H₂S found

in the fluids (Kelley et al., 2001, 2005). Methane and H₂ concentrations are also elevated relative to basalt-hosted MOR systems (Table 1).

Hydrothermal structures MOR sulfide deposits

When acidic hydrothermal fluids rich in reduced chemical species interact with cold, oxygenated seawater, minerals rapidly precipitate out of solution forming large deposits (reviewed in Juniper and Tebo, 1995). Mineral phases found in these deposits include sulfides, sulfates, oxides, hydroxides, silicates, and carbonates. Deposit formation can occur in the subsurface as the fluids ascend through oceanic basalt and mix with infiltrating seawater or directly on the seafloor as high temperature fluids erupt into bottom seawater. Subsurface precipitation of minerals generates stockwork deposits in the shallow crust and results in low-temperature venting on the seafloor. Low-temperature fluids are generally low in metal sulfides and as a result, precipitate oxides upon reaching the seafloor. In contrast, fluids that have not been diluted and cooled in the subsurface rapidly precipitate metal sulfides such as pyrite (FeS₂), chalcopyrite (CuFeS₂), and sphalerite (ZnS) upon mixing with seawater. Precipitation of metal sulfides results in the appearance of “black smoke” and ultimately forms massive sulfide deposits (>60% sulfide minerals). Several types of sulfide features are found in vent fields, with the most spectacular being the black smoker chimney (Figure 3a). Other sulfide structures generated at marine hydrothermal vents include diffuse flow beehives, flanges, and complex flow sulfide mounds (Van Dover, 2000). In all cases, active sulfide features provide extreme physical and geochemical gradients that

sustain diverse microbial populations even after fluid flow has ceased.

Lost City carbonate deposits

In contrast to the sulfide structures found along basalt-hosted MOR systems, hydrothermal fluids venting at Lost City produce large white chimneys and flanges composed primarily of aragonite ($CaCO_3$) and brucite ($Mg(OH)_2$) (Figure 3b) (Kelley et al., 2001). Active structures are highly porous and emit fluids from complex networks of centimeter sized channels (Kelley et al., 2005). Extinct structures are less porous resulting from the replacement of aragonite with calcite ($CaCO_3$) and the dissolution of brucite. The largest structure at Lost City, Poseidon, is over 60 m tall, making it the tallest seafloor hydrothermal feature yet discovered (Kelley et al., 2001).

Microbial metabolism

The hydrothermal fluids provide the energy and nutrients for a thriving microbial ecosystem. Additionally, the porous sulfide deposits are excellent habitats for the metabolic diversity of microorganisms.

Terminology

Energy sources for microbial metabolism include light-dependent reactions (less important at deep-sea vents) and light-independent chemical reactions and are described by the prefixes photo- and chemo-, respectively. Energy sources are further classified depending on whether the source of electrons is inorganic (-litho-) or organic (-organo-). For carbon sources, the suffix -autotroph describes an organism that obtains carbon from an inorganic source (CO_2), while the term -heterotroph describes an organism that obtains carbon from an organic source. For example, a microorganism that is able to gain energy and electrons from H_2 and use this energy to fix CO_2 is referred to as a chemolithoautotroph, while humans who require organic carbon and energy sources are described as chemoorganoheterotrophs, as are many microorganisms. Some microorganisms are not obligatory autotrophs and will assimilate organic carbon substances if they are available. The term mixotroph is used to describe these organisms which appear to be common in most environments.

Microorganisms also have varying requirements for oxygen (O_2) as an oxidant. Some organisms have an

Kelley, University of Washington and the Lost City Team.

obligate need (aerobes) while others cannot tolerate O_2 at all (anaerobes). Furthermore, some organisms require low levels of O_2 (microaerophile) while others can switch between aerobic and anaerobic metabolisms (facultative anaerobe).

At deep-sea vents, the heat and pH preference provides an additional habitat selection. All microbes have a preferred temperature range at which optimal growth is achieved. Psychrophiles have optimal growth $\leq 15^\circ C$, mesophiles grow optimally between 25 and $40^\circ C$, thermophiles and hyperthermophiles grow optimally between 45 and $80^\circ C$, and $\geq 80^\circ C$, respectively.

The pH gradients at deep-sea vents can vary from as low as pH 2.5 to over pH 8.0, as the acidic hydrothermal fluid mixes with the cold seawater. Thus, there are habitats of low pH where acidophiles thrive; however, by far the majority of habitats at vents available for microbial colonization are circumneutral (pH $>6 <8$), and these organisms are therefore referred to as neutrophiles.

Energy sources

Seafloor hydrothermal ecosystems are supported almost entirely by chemosynthetic primary production fueled by the chemical disequilibrium between the oxygenated seawater and the reduced hydrothermal fluids. Microorganisms capture this energy by way of reduction/oxidation (redox) reactions in which seawater typically provides the oxidant (O_2 , SO_4^{2-} , NO_3^- , CO_2) and the hydrothermal fluids provide the reductant (H_2 , H_2S , HS^- , S^0 ,

$S_2O_2^{3-}$, Fe^{2+}). Redox reactions generate energy that is used to fix CO_2 into cellular material which then provides organic carbon for various heterotrophic microbes and animals that make up the rest of the community. Some of the most thermodynamically favorable reactions found in marine hydrothermal environments are presented in Table 2. Reactions are expressed in terms of the change in free energy (ΔG), where the more negative the value the more energy an organism will gain by catalyzing the reaction. Calculated values suggest that aerobic oxidation of reduced sulfur compounds (HS^- , S^0 , $S_2O_2^{3-}$) are the most energetically favorable and potentially the most significant reactions in terms of biomass production in marine hydrothermal environments. It is important to note, however, that thermodynamic calculations can be misleading as they do not consider the bioavailability of certain reactants and potential kinetic inhibition under different environmental conditions (Takai et al., 2006). Several past studies have attempted to model the overall energetics in a variety of marine hydrothermal systems considering such factors (McCollom and Shock, 1997; McCollom, 2000; McCollom, 2007). An interesting conclusion from a theoretical study is that four times as much energy per kg of hydrothermal fluid is available to H_2 oxidizers in ultramafic hosted systems than to sulfur oxidizers because of the increased concentrations of H_2 (McCollom, 2007). This suggests that H_2 oxidizers may be more important than sulfur oxidizers in ultramafic hosted systems (McCollom, 2007). A recent report lends support to

Hydrothermal Environments, Marine, Table 2 Examples of thermodynamically favorable redox reactions utilized by microorganisms from marine hydrothermal environments

Conditions	Electron donor	Electron acceptor	Free energy ΔG^a (kJ/mol)	Metabolic process
Aerobic	H ₂	O ₂	−237	Hydrogen oxidation
	HS [−]	O ₂	−797	Sulfide oxidation

this hypothesis, as the diversity of H₂-oxidizing bacteria was found to increase as the concentration of H₂ gas increased in vents sampled from the ultramafic hosted Logatchev vent field along the MAR (Perner et al., 2007). These studies speak to the tight coupling of geochemistry and microbial primary production in marine hydrothermal environments.

Microbial habitats and diversity

Seafloor hydrothermal systems provide several habitats over a wide range of physical environments that sustain distinct microbial communities. Such environments include active and inactive vent structures, biotic and abiotic surfaces receiving hydrothermal fluid inputs, inside vent animals (endosymbionts), and hydrothermal vent plumes (Figure 2) (reviewed in Karl, 1995a; Van Dover, 2000; Kelley et al., 2002; Takai et al., 2006). Many of these environments are exposed to varying inputs of hydrothermal fluids, resulting in fluctuating temperatures and chemistry. Below is a brief discussion of each of these habitats and their associated microbial biodiversity. These biodiversity assessments are based on growing and characterizing isolates under laboratory conditions (culturing techniques) and through molecular phylogenetic approaches that are culture-independent. This latter approach is based on extracting genomic DNA from environmental samples, and then amplifying a diagnostic phylogenetic marker for Bacteria and Archaea, the small subunit rRNA gene (16S rRNA), using the polymerase chain reaction.

Active sulfide structures

Using culture-dependent and culture-independent techniques, a rich diversity of Bacteria and Archaea have been found associated with active sulfide structures (reviewed

in Jannasch, 1995; Karl, 1995b; Kelley et al., 2002; Takai et al., 2006). Free-living microorganisms supported by active sulfide structures include mesophilic, thermophilic, and hyperthermophilic chemolithoautotrophs, heterotrophs, and mixotrophs. Organisms can be anaerobes, facultative anaerobes, microaerophiles, and obligate aerobes.

In general, Bacteria are the most numerically abundant microorganisms associated with active sulfide structures (reviewed in Jannasch, 1995; Karl, 1995b; Kelley et al., 2002; Takai et al., 2006). Their abundance can range anywhere from 35 to 99% of the microbial population, depending on the method used to measure abundance, the type of vent feature, and where within a chimney structure one examines (Harmsen et al., 1997; Takai and Horikoshi, 1999; Takai et al., 2001; Hoek et al., 2003; Schrenk et al., 2003; Nakagawa et al., 2006).

Within the Bacteria, members of the epsilon-Proteobacteria have consistently been found to dominate microbial communities in deep-sea hydrothermal environments (Reysenbach et al., 2000; Campbell et al., 2001; Hoek et al., 2003; Nakagawa et al., 2005). These free-living deep-sea epsilon-Proteobacteria are mesophilic to moderately thermophilic. Recently, several representatives have been obtained in pure culture that are chemolithoautotrophs capable of oxidizing H₂ and sulfur compounds while using O₂, NO₃[−], or sulfur compounds as terminal electron acceptors (reviewed in Campbell et al., 2006). Like in cave environments, the epsilon-Proteobacteria play an essential role in sulfur cycle at deep-sea vents.

Other commonly identified but less abundant bacterial members of the free-living microbial communities include the thermophilic *Aquificales* and *Thermotogales* (reviewed in Miroshnichenko and Bonch-Osmolovskaya, 2006). The *Aquificales* are globally distributed in marine

hydrothermal environments but are restricted to active sulfide structures and hydrothermal fluids due to their thermophilic lifestyle. They are generally chemolithoautotrophs and chemoorganotrophs capable of oxidizing H_2 , S^0 , and $S_2O_3^{2-}$ either aerobically or anaerobically (NO_3^- or sulfur compounds) (Reysenbach, 2001a). The *Thermotogales*, on the other hand, are strictly anaerobic, thermophilic heterotrophic fermenters (Reysenbach, 2001b).

As stated above, Archaea are less abundant in active sulfide structures, yet they play a key biogeochemical role especially at the higher temperatures. Some of the most exhaustive studies on microbial diversity at deep-sea vents have focused solely on the Archaea revealing a high phylogenetic and metabolic diversity within this domain (Takai and Horikoshi, 1999; Takai et al., 2001; Nercissian et al., 2003; McCliment et al., 2006). Most of the Archaea found here are thermophilic to hyperthermophilic and are thus restricted to areas most influenced by hydrothermal fluids. Within the Archaea, the two main phyla, the Crenarchaeota and Euryarchaeota, are well represented, while the enigmatic "Korarchaeota" and "Nanoarchaeota" are rarely detected (reviewed in Takai et al., 2006).

Crenarchaeota commonly detected at active sulfide structures include cultivated members of the Desulfurococcales (e.g., *Pyrodictium* and *Pyrolobus*) and several uncultivated groups such as the deep-sea hydrothermal vent crenarchaeotic group (DHVC1), and the marine group I (Takai and Horikoshi, 1999; Takai et al., 2006). *Pyrodictium* is an example of a hyperthermophilic mixotrophic organism with the ability to use either H_2 or complex organics to reduce elemental sulfur (reviewed in Reysenbach et al., 2002). *Pyrolobus* is also a hyperthermophile but, unlike *Pyrodictium*, *Pyrolobus* is an obligate chemolithoautotroph that can only use H_2 to reduce nitrate (NO_3^-), thiosulfate, ($S_2O_3^{2-}$) or O_2 .

Euryarchaeota commonly found at marine hydrothermal systems include the hyperthermophilic methanogens (*Methanocaldococcus* spp.), the hyperthermophilic SO_4^{2-} reducing *Archaeoglobales*, and a variety of thermophilic fermentative *Thermococcus* species (Takai and Horikoshi, 1999; Takai et al., 2006). While these are readily grown in the laboratory, their relative abundance in the environment has been shown to vary from one site to another (Reysenbach et al., 2000; Takai et al., 2001; Hoek et al., 2003; Nercissian et al., 2003; McCliment et al., 2006). Several lineages often detected at vent sites around the globe have been classified as the Deep-sea Hydrothermal Vent Euryarchaeotal Groups (DHVEG) (Takai and Horikoshi, 1999; Reysenbach et al., 2000; Takai et al., 2001; Hoek et al., 2003; Nercissian et al., 2003). Several subdivisions exist within this group but at least one lineage, the DHVEG-2, appears to be endemic to deep-sea vents. Little was known about this lineage until Moussard et al. (2006) showed optimal activity and thermostability of a DNA polymerase belonging to this lineage which suggested a thermophilic lifestyle. Thermophily was confirmed when the first isolate

was obtained in pure culture (Reysenbach et al., 2006). The organism, *Aciduliprofundum boonei*, is a heterotrophic thermoacidophile capable of fermenting peptides and reducing Fe and S. Isolation of this organism was significant because it is the first obligate acidophile isolated from a deep-sea vent and the first member of the DHVEG-2 lineage to be grown. Prior to this discovery, the absence of acidophiles from a deep-sea vent had always puzzled microbiologists as hydrothermal fluids are acidic, and geochemists had predicted the presence of acidic microhabitats within sulfide chimneys (Von Damm, 1995; Tivey, 2004).

Inactive sulfide structures

Hydrothermal fluid flow through individual sulfide structures is temporary as subsurface flow paths constantly change and chimneys collapse. Inactive sulfides are subjected to low-temperature oxidative weathering in which the reduced sulfur moiety is converted to soluble SO_4^{2-} and the metals, mostly Fe, are converted to insoluble oxyhydroxide crusts (Juniper and Tebo, 1995). Oxidation occurs abiotically as oxygenated seawater penetrates the rock, but can also be mediated by S- and Fe-oxidizing bacteria (reviewed in Edwards, 2004; Edwards et al., 2005). While microbial mediated sulfide weathering in terrestrial systems has been studied for decades, this area of research is in its infancy in the deep sea (Edwards et al., 2003a, b; Edwards, 2004; Rogers et al., 2003; Suzuki et al., 2004). Culturing studies have resulted in the isolation of several psychrophilic, neutrophilic Fe-oxidizing bacteria belonging to the alpha- and gamma-divisions of the Proteobacteria from sulfide rocks collected along the Juan de Fuca Ridge (Edwards et al., 2003a). A follow-up study with one of the gamma-Proteobacteria isolates showed that the organism promoted the dissolution of native sulfide minerals under anaerobic conditions (Edwards, 2004). Although the mechanism of dissolution remains unclear, these studies illustrate that Fe-oxidizing bacteria are associated with extinct sulfide minerals on the seafloor and can actively promote the dissolution of these minerals at least in the laboratory.

Carbonate structures of Lost City

Microbial communities found in active carbonate structures at the Lost City vent field differ from those found in active sulfide structures due to the contrasting physical and geochemical conditions. Inner portions of carbonate chimneys in contact with hydrothermal fluids tend to be covered by thick microbial biofilms dominated by a single Archaeal phylotype belonging to the Methanosarcinales (Schrenk et al., 2004; Brazelton et al., 2006). The Methanosarcinales are the most metabolically diverse of all the methanogens, with various representatives known to generate CH_4 from acetate and H_2/CO_2 or by dismuting methyl compounds (Boone et al., 2001). Members of the Methanosarcinales also participate in a nonobligatory syntrophic relationship

with SO_4^{2-} reducing bacteria that results in the anaerobic oxidation of methane (AOM) in oceanic cold seep environments (Orphan et al., 2001). A second archaeal phylotype belonging to the closely related ANME-1 was identified in weakly flowing and extinct carbonate chimneys (Brazelton et al., 2006). Like the Methanosarcinales, the ANME-1 are involved in AOM but appear to mediate this process without a SO_4^{2-} reducing partner and at lower temperatures (Orphan et al., 2002). As the Methanosarcinales and the ANME-1 found at Lost City were only identified by molecular techniques, it is difficult to speculate on whether they are producers or consumers of CH_4 .

In contrast to the Archaea, Bacteria appear to be more diverse in active and inactive carbonate chimneys (Brazelton, et al., 2006). The most diverse bacterial group at Lost City is the gamma-Proteobacteria which includes close relatives of known chemolithoautotrophic S- and HS^- -oxidizers (e.g., *Thiomicrospira* spp.) and several methylophilic (CH_4 -oxidizing) genera (e.g., *Methylobacter*, *Methylomonas* and *Methylophaga*). Other chemolithoautotrophic S-oxidizing bacteria belonging to the epsilon-Proteobacteria are also found at Lost City.

Perhaps the most interesting trend in bacterial diversity observed at Lost City is not what is present but what has not yet been detected. Specifically, neither any known thermophilic H_2 -oxidizing Bacteria (i.e., *Aquificales*; common in most deep-sea and terrestrial hot spring environments) nor members of the delta-Proteobacteria (the SO_4^{2-} -reducing syntrophs found in other AOM environments), were identified in carbonate chimneys (Brazelton et al., 2006). The lack of bacterial H_2 oxidizers is unexpected as geochemical modeling suggests that H_2 oxidation provides four times as much energy per kg of hydrothermal fluid than S oxidation in ultramafic hosted systems (McCollom, 2007). This suggests that available energy may not be the main constraint driving which microbial metabolisms can be supported in particular environments. It is important to note, however, that relatively few studies have been conducted at Lost City and that these observed trends may be due to the lack of adequate sampling or incorrect inferences based solely on 16S rRNA gene similarity.

Biotic and abiotic surfaces

Microbes are opportunistic organisms and will colonize any surface where growth substrates are provided. In areas influenced by hydrothermal fluids, this includes the sulfide deposits as described above and surfaces of invertebrate animals (reviewed in Van Dover, 2000). Some of these relationships are commensal as the host does not appear to gain an advantage by being colonized while others truly are symbiotic (episymbiosis), with both the host and microbes benefiting. An example of a commensal relationship is found between the giant tube worm *Riftia pachyptila* and the diverse microbial communities that colonize the outside surfaces of its chitinous

tube (López-García et al., 2002). Most of the microbes identified on the outside of the tube are members of the ubiquitous epsilon-Proteobacteria and are likely oxidizing the reduced sulfur compounds in the hydrothermal fluids. An episymbiotic relationship is found on the polychaete worm *Alvinella pompejana* (Van Dover, 2000). *Alvinella pompejana* lives in tubes on the sides of black smoker chimneys where water temperatures can exceed 70°C (reviewed in Desbruyeres et al., 1998). It has a fully functional digestive system and appears to feed upon microbial mats inside of its tube as well on sulfide surfaces. The worm also houses diverse microbial communities on its dorsal surfaces including microaerophilic H_2S -oxidizing members of the epsilon-Proteobacteria. Although the exact nature of this relationship is unknown, it is thought that the bacteria may detoxify H_2S or provide nutritional supplement to the worm.

In addition to surfaces of vent animals, microbes often colonize rocks and sediments surrounding hydrothermal vents. These environments are primarily sustained by hydrothermal fluids flowing diffusely through the underlying porous sediments. The most well-studied and possibly most diverse microbial mat system found in marine hydrothermal environments is in the sediment-hosted Guaymas Basin. Microbes found here include thermophilic/mesophilic methanogens and methanotrophs (Dhillon et al., 2005), SO_4^{2-} reducing Bacteria (Kallmeyer and Boetius, 2004), H_2S -oxidizing gamma-Proteobacteria (Nelson et al., 1989), and even spore forming Mn-oxidizers (Dick et al., 2006). Much of this diversity is fueled by the presence of overlying sediments which provides different combinations of organic/inorganic substrates typically not found in non-sediment-hosted systems.

Endosymbionts

Several invertebrate animals form obligate symbiotic relationships in which the bacteria are hosted inside the animal cells. The most well-studied example is in the giant tube worm *Riftia pachyptila* (reviewed in Minic and Hervé, 2004). As adults, *Riftia* completely lack a mouth, the digestive system and anus and are sustained by chemoautotrophic H_2S -oxidizing Bacteria belonging to the gamma-Proteobacteria (Cavanaugh et al., 1981; Felbeck, 1981; Jones, 1981; Minic and Hervé, 2004). In this relationship, *Riftia* provide the bacteria with inorganic carbon, O_2 , H_2S , and NO_3^- and, in turn are provided with organic carbon. Other invertebrate organisms such as the giant clam *Calypotgena magnifica* and the mytilid mussels *Bathymodiolus* spp. also house H_2S -oxidizing endosymbionts in their gill tissues (Van Dover, 2000). The symbiotic relationship between mussels and bacteria, however, is not obligate as they retain some of their filter feeding capabilities. In addition, certain species of *Bathymodiolus* have methanotrophic (CH_4 -oxidizing) endosymbionts and even dual symbionts with both sulfur- and CH_4 -oxidizing bacteria.

Hydrothermal plumes

Upon reaching neutral buoyancy, hydrothermal vent plumes carrying elevated concentrations of S, metals (Fe and Mn), H₂, and CH₄ extend hundreds of meters laterally into the water column. Not surprising, elevated biomass has been detected in plumes, suggesting that these environments are areas of high productivity (reviewed in Winn et al., 1995). Methane oxidation has been measured in plume waters collected along the Juan de Fuca Ridge, further supporting microbial activity in vent plumes (DeAngelis et al., 1993). More recently, Sunamura et al. (2004) used culture-independent techniques to assess the diversity of microbes in plumes over the Suiyo Seamount. Members of the gamma- and epsilon-Proteobacteria were dominant in the plume waters and are likely using reduced sulfur compounds because of their close phylogenetic relationship with known sulfur-oxidizers (Sunamura et al., 2004).

The first aerobic anoxygenic photosynthetic bacteria from the deep sea were isolated from plumes (Yurkov and Beatty, 1998). These organisms belong to the alpha-Proteobacteria and appear to supplement heterotrophic growth with photosynthesis under laboratory conditions. Their presence in deep-sea hydrothermal environments seems puzzling because of the lack of sunlight, but high-temperature fluids (≈350°C) have been detected to emit photons capable of supporting facultative photosynthetic bacteria (Van Dover et al., 1996). Their role and significance in the environment, however, remain unknown.

Conclusions

Although we know significantly more about the diversity of microorganisms from deep-sea vents since their discovery in the late 1970s, we still have a rudimentary understanding of their ecology and geobiology. Recently, the discovery of acidophiles (Reysenbach et al., 2006), high-temperature nitrogen fixation (Mehta and Baross, 2006), and high-temperature Fe reduction (Kashefi and Lovley, 2003) provided additional insights into the roles microbes play in biogeochemical cycling at vents. Furthermore, studies are now being undertaken to explore the temporal changes that occur in the microbial communities as the available carbon and energy sources change (e.g., Pagé et al., 2008). Whether these changes are due to the in situ biological activity or due to the geochemical constraints of the hydrothermal fluids and mixing and subsurface reaction zones is still unknown. It is clear that deep-sea vents represent one of the few places on Earth where the “bio” is so tightly coupled to the “geo.”

Definition

Hydrothermal Environments, Terrestrial. Areas on the Earth's surface that are under the influence of geothermal waters, steam, and associated gases discharged from hot springs, geysers, and fumaroles.

Introduction

Terrestrial hydrothermal environments are those settings where fluids discharge either at or close to the land surface at a temperature that is significantly above the local ambient air temperature. The hydrothermal processes transfer heat and dissolved matter to the surface in a liquid or vapor (gas) phase. Those fluids originate at variable depths below the Earth's surface and have a wide range of temperature and chemical composition. Visible features of terrestrial hydrothermal environments include hot springs, geysers, fumaroles, and steam vents. Travertine (calcite and aragonite: CaCO_3) and sinter (mainly opal-A: $\text{SiO}_2 \cdot n\text{H}_2\text{O}$), precipitated from thermal water, commonly form mounds and terraces around many spring and geyser vents. In contrast, chemical reactions between acidic hydrothermal fluids and the host bedrock and soils usually produce extensive hydrothermal alteration that generates a very different type of landscape.

Since the pioneering studies of life in hydrothermal environments, begun in the 1960s by Brock (1978) and colleagues, interest in these environments has increased significantly for many reasons (Bock and Goode, 1996; Renaut and Jones, 2000; Jones and Renaut, 2003a). The extremophiles that inhabit modern high-temperature settings, which include thermophiles and thermoacidophiles, have implications for understanding the origin of life on the Earth and potentially on other planets. Many of the rocks precipitated around hot springs have stromatolitic fabrics and contain numerous fossilized microbes. Many recent studies have tried to determine if such microbes

directly influence mineral precipitation, or are simply trapped in essentially abiotic mineral deposits. From a geological perspective, surface hydrothermal environments can provide clues to subsurface processes including the potential for epithermal ore mineralization and for geothermal energy development (Pirajno, 1992; Bogie et al., 2005).

Geothermal fields

The geothermal gradient, a measure of the increase in temperature with depth in the Earth's crust, has an average value of $25\text{--}30^\circ\text{C km}^{-1}$, but this may rise to several hundred $^\circ\text{C km}^{-1}$ in regions of volcanic activity. Geothermal systems are found in regions with normal and slightly elevated geothermal gradients, but high-temperature systems are most common in regions of active tectonics and volcanism near plate margins (Figure 1). Although geothermal fields can extend over several thousand square kilometers, the individual surface areas of hydrothermal discharge tend to be localized and of limited extent within those domains.

Using stable isotopic evidence, Craig (1963) confirmed that most hydrothermal fluids are meteoric in origin. Some hydrothermal systems are partly fed by connate (formation) waters that were buried along with the host sediments; other hydrothermal fluids may derive from juvenile (magmatic) and metamorphic waters, but these are usually minor components if present (Nicholson, 1993; Giggenbach, 1994).

The fluids that feed high-temperature (high-enthalpy) liquid-dominated hydrothermal systems derive mainly from cool meteoric water that has circulated to a few kilometers depth (up to ~ 5 km) via faults, fractures, and permeable horizons. The heated fluids react with host rocks, acquire solutes, and typically evolve to become saline ($3,000\text{--}5,000 \text{ mg kg}^{-1}$) and chloride-rich, forming geothermal reservoirs with temperatures of up to $\sim 400^\circ\text{C}$. Those fluids then rise convectively and may boil with the decreasing pressure during ascent to create a two-phase (steam + liquid) zone below the land surface. The liquid phase may discharge at the surface as hot springs, whereas the vapors released on boiling (steam separation) may discharge at the surface as fumaroles. Rising hot fluids may mix with shallow groundwaters before surface discharge, which may modify their composition and temperature. Not all geothermal systems are of high-temperature type. In low-temperature (low-enthalpy) systems, the reservoir temperature may be $<150^\circ\text{C}$, and the fluids may not boil before being discharged as springs.

Thermal fluids

Geothermal fluids are commonly classified according to their dominant anion, into chloride waters, sulfate waters, and bicarbonate waters (Table 1) (Henley and Ellis, 1983; Nicholson, 1993). Waters of mixed anion composition are also found. The composition of the discharged fluids

profoundly affects the characteristics of the terrestrial surface environment, including any mineral deposits and hydrothermal alteration, and the biota that inhabit the areas of hydrothermal discharge.

Chloride waters (also termed “alkali-chloride” or “neutral chloride” waters)

These saline waters typify the deep geothermal fluids in most high-temperature geothermal systems and where discharged at the surface, they commonly overlie permeable zones of major thermal upflow (Nicholson, 1993).

They have near neutral pH and are chloride-rich with variable SO₄²⁻ and HCO₃⁻ concentrations. Chloride waters are typically rich in dissolved silica and have Na⁺ and K⁺ as the dominant cations. Carbon dioxide is usually the main dissolved gas with much lower amounts of H₂S.

At the land surface, chloride fluids commonly discharge from hot and boiling springs, often with clear bluish-green waters, and from most geysers (Figure 2a). Such fluids characteristically precipitate large quantities of silica sinter (see Chapter Sinter). If the fluids are rich in HCO₃⁻, they may boil at greater depths and may

precipitate both sinter and travertine upon CO₂ degassing at the land surface.

Spectacular examples of geysers and springs that eject chloride waters are found in most of the major geothermal sites, including those in Yellowstone National Park (Bryan, 2008), the Taupo Volcanic Zone of North Island, New Zealand (Ellis and Mahon, 1977; Jones and Renaut, 2003b), El Tatio in northern Chile (Cusicanqui et al., 1976; Fernandez-Turiel et al., 2005), and Iceland (Torfason, 1985). The sinter that precipitates around many geyser and spring vents and on their discharge aprons as mounds and terraces is commonly colonized by diverse, varicolored, microbial communities.

Sulfate waters ("acid sulfate waters")

Sulfate-rich waters form through condensation of geothermal gases in shallow oxygenated groundwater. Steam, gases, and other volatiles (e.g., NH₃, As, B) that were originally dissolved in deep geothermal fluids can separate from chloride waters when they undergo boiling at depth, and rise toward the surface. The steam-heated acidic waters commonly boil at the water table because the separated steam contains high enthalpy from the deeper geothermal fluid.

Sulfate, the dominant anion, is formed by oxidation of condensed hydrogen sulfide (Nicholson, 1993):

The protons produced may be supplemented by condensation of CO₂ to create acidic waters:

The pH is typically between 2.8 and ~5. Chloride is usually present in minor amounts. Bicarbonate is usually absent because it is lost from solution as CO₂ gas. These acidic fluids, typically present above the water table close to the land surface (<100 m depth), are usually found around the margins of geothermal fields at sites distant (few hundred meters to several kilometers) from the main chloride-rich upflow.

Acidic waters form distinctive surface environments characterized by hot springs, turbid boiling mud pools, or steaming ground commonly with extensive pits and collapse features resulting from hydrothermal alteration (Figure 2b). The acidic waters leach the host rocks

Hydrothermal Environments, Terrestrial, Figure 2 Variations in modern hydrothermal environments according to water chemistry. (a) Hot springs, geysers, and extensive silica sinter coating a fault scarp at Orakeikorako, New Zealand. The fluids are alkaline chloride waters. (b) Muddy hot springs and fumaroles at Myvatn, northern Iceland. The fluids are acid sulfate in composition. Hydrothermal alteration of young volcanic rocks has produced extensive clays and Fe oxides at the land surface. (c) Boiling hot spring and perpetually spouting hot spring (*right*) rimmed by calcite travertine on the shoreline of Lake Bogoria, Kenya. The spring water is of sodium bicarbonate composition. (d) Small geyser discharging mixed acid chloride-sulfate waters (pH: 2.1–2.6) near Hakereteke Stream, north Waiotapu, New Zealand. Thin Fe-rich sinter covers the substrate.

producing extensive clays (mainly kaolinite), commonly with alunite, alunogen, jarosite, Fe-oxyhydroxides, pyrite, cristobalite, and native sulfur. Little sinter forms in acidic waters, but alteration of volcanic rocks by sulfuric acid can leave behind abundant opaline silica in place, termed “silica residue” (Rodgers et al., 2002). Well-developed examples of acid sulfate water discharge are found at Tikitere (New Zealand), Myvatn (northern Iceland), and Norris Geyser Basin (Yellowstone National Park).

Bicarbonate waters

Bicarbonate-rich hot waters are formed mainly when steam and gases (mainly CO_2) condense in shallow groundwaters. Although most common around the margins of geothermal fields, they may also form in sites distant from volcanic activity. They often form where geothermal fluids are in contact with limestone or volcanic bedrock. Such fluids normally have a near-neutral pH when discharged. The initial acidity of the rising CO_2 -rich fluids is neutralized by hydrolysis reactions with bedrock that consume protons (H^+) leaving waters dominated by HCO_3^- and Na^+ . Sulfate and chloride have variable concentrations. At the land surface, these fluids discharge from springs that range from warm to boiling and most have clear water. Travertine deposits, composed of calcite and (or) aragonite, commonly form around the vent and downslope of these springs (Figure 2c) where sufficient Ca^{2+} is available. Sinter is generally absent, but minor amounts can form from very hot and boiling bicarbonate waters. Hydrothermal alteration at the surface is generally very minor, though more extensive at depth.

Carbonate deposits associated with such springs may be localized around their vents or form vast discharge aprons. Examples include the large terrace mounds, fissure ridges, and related features at Pamukkale in Turkey, Mammoth Hot Springs in Wyoming, and at many sites in central Italy (Bargar, 1978; Chafetz and Folk, 1984; Pentecost, 2005). The travertines precipitate from bicarbonate waters over a wide temperature range, from ambient to boiling. Most carbonate precipitation has been attributed to rapid loss of CO_2 upon discharge of the spring waters at the land surface (Renaut and Jones, 1997; Pentecost, 2005). Microorganisms, principally cyanobacteria, may play a role in some carbonate precipitation through photosynthetic removal of CO_2 , but at high temperatures most precipitation is probably driven by abiotic degassing of carbon dioxide.

Mixed waters

Waters that contain two anions with similar concentrations form by several different processes. *Sulfate-chloride waters* typically have a pH of ~ 2 –5, but can have a pH as low as 0. They originate through subsurface mixing of sulfate and chloride waters, oxidation of H_2S in chloride waters, near-surface condensation of volcanic gases in meteoric waters, or dissolution of sulfate-bearing bedrock by migrating thermal chloride waters (Nicholson, 1993).

Such waters discharge as warm to hot springs, commonly with thin sinter deposits and sulfate-bearing minerals around the vent. Native sulfur may also be present.

Examples of acidic sulfate-chloride springs are found in the northern part of the Waiotapu geothermal area of North Island, New Zealand (Figure 2d) (Jones and Renaut, 2006). These springs discharge waters a pH of 2.1–2.6 at temperatures $>90^\circ\text{C}$. Spicular sinters containing silicified microbes have precipitated around these springs together with kaolinite, jarosite, and gypsum.

Dilute *chloride-bicarbonate* waters form where chloride waters have been diluted by groundwater or bicarbonate water (Nicholson, 1993). They typically are found in springs of variable temperature around the margins of thermal upflow zones, but waters of this composition also discharge in low-temperature systems. The fluids are typically Cl-dominated, have variable HCO_3^- concentrations, and a neutral pH of 6–8. Minor travertine and (or) sinter may form around the vents, but many of these springs lack surface deposits.

Types of geothermal systems

The environmental characteristics of terrestrial hydrothermal sites are strongly controlled by the type of geothermal system that supplies their fluids. Many classifications of geothermal systems have been proposed (e.g., Heiken, 1982; Henley and Ellis, 1983; Pirajno, 1992; Nicholson, 1993). Kühn (2004) recognized two major groups. In *static systems*, heat may be transferred to the surface by conduction without convective fluid movement. In *dynamic systems*, heat is transferred to the surface by moving fluids undergoing convective circulation.

Static (conductive) geothermal systems

Static geothermal systems depend on above-average conductive heat flow in the crust. In static magmatic systems, fluids can be heated by granitic plutons. Other conductive systems are hosted by porous sedimentary rocks in deep sedimentary basins. Static systems generally have little impact at the surface. However, trapped formation waters, which are typically saline, chloride-rich and have temperatures of ~ 70 – 150°C , can be released by tectonic movements and discharge at the surface as thermal springs with variable temperature and salinity, depending on the degree of mixing with shallow groundwaters. Many examples are known from Europe, especially Germany (Kühn, 2004).

Dynamic (convective) geothermal systems

Most high-temperature geothermal systems are linked to magmatic intrusions (volcano-plutonic and volcanic), which provide the heat that drives the convective circulation. In such systems, reservoir temperatures are commonly $>150^\circ\text{C}$ at depths of a few kilometers. Such systems are most common in sites of geologically young volcanism and in tectonically active regions such as areas of faulting, rifting, and caldera collapse, and at plate

margins in general. As in other hydrothermal systems, the waters are predominantly meteoric, and the ascending fluids commonly boil before or during surface discharge. The hydrothermal systems vary with tectonic location and type of volcanism (Pirajno, 1992). Many are associated with silica-rich and andesitic volcanism, whereas others are associated with basaltic volcanism.

Silica-andesitic systems

High-temperature hydrothermal systems associated with silica-rich volcanism are highly variable. Some systems are liquid dominated, producing springs and geysers, whereas others are vapor dominated, generating mainly steaming ground and fumaroles at the land surface.

In regions of low relief (Figure 3a), magmatic systems supply heat and gases to meteoric groundwater and give rise to convective columns that can allow deep chloride-rich waters to flow directly to the surface (e.g., Taupo Volcanic Zone, New Zealand). The deep fluids may discharge as springs and geysers above the main upflow or may move laterally some distance away from upflow column. Steam zones commonly develop in sites marginal to the main upflow. Oxidation of H_2S and other gases in groundwater produces acid sulfate waters, generating fumaroles and steaming ground. Condensation of CO_2 in groundwater may produce neutral to alkaline bicarbonate springs around the margins of the field from which travertine may be formed. These types of system commonly have fumaroles, steaming ground, and both acid and alkaline springs located near each other because of the low topographic relief and limited potential for lateral flow of fluids near the land surface.

In areas of high relief (Figure 3b), such as andesitic stratovolcanoes, a thick two-phase zone (liquid–steam–gas) commonly develops below the land surface. At high elevations, fumaroles, steam vents, and acid sulfate springs fed by condensate are common features. Deep chloride-rich waters normally do not reach the surface but may flow laterally and mix with groundwater or cooled, descending sulfate waters before discharging as hot springs on the volcano flanks or other areas of relatively low relief. Numerous examples are found in Indonesia, the Philippines, and Japan.

Some silicic systems are vapor dominated (e.g., Lardarello, Italy; The Geysers, California). The deep thermal reservoir contains steam, probably fed by saline boiling water, most of which is contained in convective cells capped by low-permeability rocks. Fluids escaping the reservoir produce steaming ground and fumaroles at the surface and some thermal springs similar to those in high-relief regions. Surface fluids can be of acid sulfate or bicarbonate type.

Basaltic systems

High-temperature basaltic systems occur at mid-oceanic ridges (see Chapter *Hydrothermal Environments, Marine*) and in continental rifts. Many tectonic and hydrogeological settings are possible (Pirajno, 1992), but

in most examples hydrothermal fluids rise along permeable faults discharging at hot springs and geysers on the rift basin floor (Figure 2c), including subaqueous discharge on the floors of lakes. Fluid compositions are variable and depend partly on the bedrock composition, which may be volcanic, basement rocks, or valley-fill sediments.

Low temperature systems

Low-temperature geothermal systems are common and of diverse origins. Most are characterized by dilute waters that are discharged as springs with maximum temperatures of about 30–60°C. They form in regions of both normal and above-average heat flow. They are common where meteoric fluids return to the surface having been heated to temperatures above ambient surface temperature. These springs commonly occur in regions of deep faulting and folding, in regions of tectonic uplift where hot rocks have been elevated to higher levels in the crust, and from the residual heat of cooling plutons (Nicholson, 1993). Meteoric fluids circulate at depth through faults, fractures, and permeable rocks. The chemical composition of the fluids reflects such factors as the bedrock mineralogical composition, depth and temperature of fluid circulation, the rates of recharge, and degree of mixing with near-surface waters before discharge. Such low-enthalpy systems are common in western Canada, Europe, Australia, and on most continents.

The surface environment in hydrothermal areas

Areas of hydrothermal discharge are distinctive features of the landscape. Where they are extensive, they can influence the local ecology at all scales, from large mammals to microbes. The impact of hydrothermal discharge at the land surface ranges from negligible, where dilute warm springs flow quietly from small vents at temperatures little above ambient, to major, where high-temperature and acidic fluids destroy vegetation, precipitate mineral deposits, or flood the landscape. In general, areas of neutral to alkaline hydrothermal discharge are mainly constructive with new rocks (sinter, travertine, and others) precipitated from hydrothermal fluids upon an existing landscape (Figure 2a, c). In contrast, where the fluids are mainly acidic, the net impact on the surface environment is often destructive and the landscape commonly becomes nearly barren and pock-marked by craters that result from collapse due to hydrothermal alteration of the host bedrock or hydrothermal explosions (Figure 2b, d). The main hydrothermal surface features are hot springs and geysers, fumaroles, steam vents, and mudpots. Some hydrothermal springs also discharge on the floors of lakes.

Hot springs

Hot springs are sites where geothermally heated groundwater discharges at the land surface (see Chapter *Hot Springs and Geysers*). There is no universally accepted definition of a hot spring (Pentecost et al., 2003). Some definitions place the lower temperature limit at an

Hydrothermal Environments, Terrestrial, Figure 3 General models of liquid-dominated magmatic geothermal systems showing relationships between subsurface fluid evolution and associated surface environments. (a) Liquid-dominated system in a low-relief setting. Inset expands the upper left half of the figure to show how surface environments and deposits vary spatially according to the type of fluid being discharged. (b) Liquid-dominated system in a high-relief (stratovolcano) setting. Adapted from figures by Henley and Ellis (1983) and Nicholson (1993).

arbitrary value (e.g., human body temperature: $\sim 37^{\circ}\text{C}$; or some fixed value: 20° , 35° , 50°C , etc.), whereas others define a hot spring by its temperature relationship to local ambient surface water temperature, mean air temperature, or a similar environmental factor. As generally used, the term hot spring is given to those springs that discharge at between $\sim 35^{\circ}\text{C}$ and the local boiling point.

Individual hot springs vary greatly in size (<10 cm to ~ 80 m in vent diameter), depth, shape, and discharge. The most common forms are circular and subcircular pools where water flows from poorly consolidated sediments or hydrothermally altered ground (Figure 4a). Very large hot springs include Grand Prismatic Spring at Yellowstone National Park and Champagne Pool at Waiotapu in New Zealand. Some large springs are composite with multiple vents discharging into a single basin (e.g., Frying Pan Lake, Waimangu, New Zealand). In contrast, shape and size can be highly irregular where flow emanates from a resistant substrate such as volcanic bedrock or from faults and fractures (Figure 4b, c). In the latter case, for example, the vents may be linear fissures without a pool. The vent morphology may change through time as pools coalesce or contract with changes, for example, in surface discharge and earthquake activity.

Geysers (Figure 4d) are hot springs characterized by intermittent turbulent discharge of water that is induced by a vapor phase of gases (mainly steam) that results from boiling. Geysers are rare (Figure 1), with more than 50% of all known geysers in Yellowstone National Park, Wyoming, USA (Bryan, 2005). Well-known geysers include Geysir in Iceland (eponym for geyser) (Torfason, 1985), Old Faithful in Yellowstone National Park (Bryan, 2008), and Pohutu at Whakarewarewa in New Zealand (Jones and Renaut, 2003b). Intermittent springs flow periodically but discharge quietly and lack the forceful ejection of a true geyser. Some springs, termed perpetual spouters (Figure 4e), erupt jets of water and steam constantly, but lack the periodicity of geysers.

Springs also change in morphology as minerals are precipitated in and around their vents (see Chapter Sinter). Mineral precipitation commonly begins around pool margins with build up of a pool-rim dam (Figure 4a), which, depending on hydrostatic pressure, may raise the water level. Water overflowing the dam may then precipitate minerals to form terraces (rimstone dams and pools), oncoids, pisoids, and a range of other spring deposits (Jones and Renaut, 2003a; Pentecost, 2005). At some springs, including many geysers, vents may grow upward forming a range of conical mound deposits (Figure 4d). Microorganisms are commonly fossilized in the spring deposits, and some have been implicated in mineral precipitation.

Fumaroles (steam vents) and mudpots

Fumaroles are vents or openings in the ground that discharge hot water vapor (steam) and (or) volcanic gases. Fumaroles are common features of active volcanoes,

where they can attain temperatures of $>900^{\circ}\text{C}$, but much cooler ($<150^{\circ}\text{C}$) vents are also present at dormant and recently extinct volcanoes and at some high-temperature spring sites, mainly in areas where the water table is relatively low. Fumaroles emit mainly steam (typically $>90\%$), carbon dioxide, and lesser amounts of sulfur (especially H_2S) and chlorine compounds. Minor carbon monoxide, ammonia, boron and fluorine compounds are present in some gases. The predominant steam is mainly superheated groundwater, whereas much of other gas is magmatically sourced. *Solfataras* are areas where fumaroles discharge large volumes of sulfur gases; *mofettes* discharge carbon dioxide, sometimes methane, from fumaroles at temperatures below boiling point of water but above those of ambient air. Mofette gases trapped in valleys and depressions can cause asphyxiation.

The impact of fumaroles on the landscape and environment reflects their abundance, gas composition, temperature, and location. Fumaroles can form on steep and low-angled slopes. On steep slopes, they typically emerge from cracks in the substrate, cm to m in scale, which may be linear, irregular, or funnel-shaped openings where gases have hydrothermally altered the bedrock. On low ground, fumaroles may pockmark the landscape with series of pits (Figure 4f), some meters in diameter. Minerals (*fumarolites*) are commonly precipitated around the vents as rock coatings, many of which are sublimates from the fumarole gases. This diverse array of minerals includes opaline silica, native sulfur, jarosite, Fe-oxyhydroxides, and many salts and rare minerals, some incorporating volatiles.

Rising steam and gases may heat the ground and condense near the land surface or may heat groundwater at shallow depth. The condensed steam and heated water may boil at the water table to produce areas of steaming ground. If H_2S is present in the vapor phase, the resulting sulfuric acid commonly attacks the bedrock and soils and may generate abundant clay minerals, especially kaolinite, producing mudpots (Figure 4g). Forceful eruption of viscous mud can produce mud volcanoes (Figure 4h). The mineralogy of mudpots has received little attention, but includes a similar suite of minerals to other acid sulfate springs.

Steam (hydrothermal) explosions

The surface environment at high-temperature hydrothermal sites occasionally undergoes major disturbances due to hydrothermal eruptions. Such eruptions have several causes but are typically related to the inability of the plumbing system to withstand high fluid pressures generated by boiling. Most eruptions result from the rapid generation of steam due to a sudden pressure reduction (Browne and Lawless, 2001). The explosive release of vapor may lead to break up of sinter or other rocks near the land surface. Blocks become strewn across the landscape, new vents may be formed, and old vents may become inactive because of the changes in the subsurface plumbing system.

(e) Perpetually spouting hot spring (pH: 8.7; T: 98.5°C) with mound of subfossil travertine, Lake Bogoria, Kenya. (f) Large (3 m wide) fumarole vent at Sol de Mañana geothermal field, southern Bolivia. (g) Boiling mudpool at Sol de Mañana geothermal field, southern Bolivia. (h) Mud volcano, Tikitere, near Rotorua, New Zealand.

The Waimangu geothermal area on North Island, New Zealand, experienced major hydrothermal explosions on April 1, 1917 that created Frying Pan Lake, with further eruptions in 1924 and 1973 (Lloyd and Keam, 1974). The 1973 eruption, for example, distributed ejecta, which consisted of hydrothermally-altered angular blocks of country rock (up to 30 cm diameter) and fine debris, over an area of $\sim 3 \text{ km}^2$.

Sublacustrine hydrothermal discharge

Thermal fluids can discharge directly from lake floors either as underwater springs or as steam and gas vents. Diffuse upward-moving steam and gases may also condense in lake water through permeable sediments without point-sourced vents. Sublacustrine springs are most common on the floors of caldera (crater) lakes, continental rift, and other tectonic lakes, and in lakes produced by subsidence, collapse, or hydrothermal eruptions in areas of acidic hydrothermal discharge. Their impact on life in the lake depends on the respective chemistry and temperatures of the lake water and thermal fluids, the rate and volume of thermal fluid discharge, and lake size, morphology, and climate, which can control seasonal stratification and hydrological closure. Like submarine springs, sublacustrine hot springs may host local communities of thermophilic organisms, and biofilms or microbial mats commonly cover the vent surfaces. Sublacustrine sinter, travertine (tufa), and other mineral deposits (e.g., metal sulfides) can precipitate around vents at sites where thermal fluids mix with lake water, undergo cooling, or exsolve noncondensable gases. Spring deposits include spires, chimneys, mounds, crusts, and various microbialites. Sublacustrine spring deposits commonly incorporate lacustrine organisms, especially planktonic diatoms and freshwater sponges, which can help distinguish them from morphologically similar subaerial spring deposits when examining ancient deposits.

Well-known examples of sublacustrine spring systems include those in Crater Lake (Oregon), Yellowstone Lake (Wyoming), Lakes Tanganyika, Kivu and Bogoria in the East African Rift, and Lake Taupo (North Island, New Zealand). Hot springs on the floor of Lake Taupo at depths of $\sim 140 \text{ m}$, for example, have produced small chimneys formed of opal-A and various Mn-, Fe-, and Hg-precipitates (de Ronde et al., 2002). Crater lakes in active and dormant volcanoes commonly receive discharge from acidic springs and fumaroles that produces acid lake waters.

Life in terrestrial hydrothermal environments

Terrestrial hydrothermal environments host many organisms, but some, notably thermophiles ($\sim 45^\circ\text{--}80^\circ\text{C}$) and hyperthermophiles ($>80^\circ\text{C}$), are unique to hydrothermal settings (see Chapter *Extreme Environments*). Although the ecology of hydrothermal environments has been studied extensively (e.g., Brock, 1978; Reysenbach et al., 2001; Robb et al., 2007; Wiegand, 2007), new discoveries continue to be made regularly. The distribution of microorganisms at hot springs and geysers is controlled mainly by temperature, pH, and water chemistry. Brock (1978) first established the main temperature tolerance ranges for the main groups of organisms in hot-spring systems (Figure 5).

Proximal areas under the influence of near-boiling water ejected from hot springs and geysers were once regarded as being sterile. The ornate and banded silica deposits commonly found around geyser vents were named “geyserite” because they were thought to have formed abiotically (Walter, 1976). It has since been shown that a diverse community of microorganisms inhabit these very hot waters (Blank et al., 2002) and that geyserite commonly contains abundant silicified microbes (Jones et al., 1997). Identifying these microbes is a challenge because many are difficult to culture and their

Hydrothermal Environments, Terrestrial, Figure 5 Upper temperature tolerance limits of selected organisms in hydrothermal environments (modified from Brock, 1978).

morphological diversity is low. DNA analyses, however, show that these extremophiles are biologically diverse (Barns et al., 2004). The hyperthermophiles are dominantly archaea, and some are also thermoacidophiles. In the hottest (anoxic) waters, the archaea are mainly chemolithoautotrophs and chemoorganotrophs, and include coccoid, rod-shaped, and filamentous forms (e.g., *Pyrolobus*, *Pyrococcus*, *Methanothermus*). Hyperthermophilic bacteria (e.g., *Aquifex*, *Geothermobacterium*), some of which are sulfide and hydrogen oxidizing species, also thrive in waters up to boiling point. Viruses also inhabit these high-temperature settings. Thin microbial films locally coat immersed rock and soil surfaces around the edge of the vents (Figure 6a), and filamentous stringers of hyperthermophiles are sometimes seen attached to the substrate in proximal outflow channels.

As water temperature decreases downstream from the spring and geyser vents, the species diversity usually increases. At temperatures between 75 and $\sim 40^\circ\text{C}$, microbial mats are commonly well developed in neutral and alkaline waters (Figure 6b). Varicoloured (green, orange, brown) microbial mats built by photosynthetic cyanobacteria often cover the substrate in sites that remain almost constantly moist from thermal outflow, and are commonly several cm thick (Figure 6c). Small coniform stromatolites form in some low-energy pools (Figure 6d, e) (Jones et al., 2002). Common genera include *Oscillatoria*, *Synechococcus*, *Phormidium*, *Anabaena*, and *Spirulina*. *Chloroflexus*, a green sulfur bacterium and anoxygenic photoautotroph, is commonly associated with these mats. Extensive extracellular polymeric gels are produced by some of these communities. Heterotrophic bacterial communities normally underlie the surface layers of these mats (Brock, 1978). Organisms common in waters cooler than $\sim 45^\circ\text{C}$ include the cyanobacteria *Calothrix* and *Pleurocapsa*, which often build nodular mats, eukaryotic algae, diatoms, fungi, and protists, some of which become important components of microbial mats.

Acid thermal areas, including areas around some fumaroles (and solfataras), usually have distinctive acidophilic communities. In acidic hot springs where the temperature is $<60^\circ\text{C}$, green mats built by the unicellular red alga *Cyanidium caldarium* are often present (Figure 6f) (Brock, 1978), together with a range of bacteria (e.g., *Thiobacillus*). Below pH 5, cyanobacteria are less abundant and mats composed of diatoms and fungi become common. Stromatolitic sinters built by diatoms, for example, are present at Frying Pan Flats at Waiotapu, New Zealand, where the pH is <3 (Figure 6g) (Jones et al., 2000).

Invertebrates, such as mat-grazing ostracods, are common in some hot spring waters that are $<45^\circ\text{C}$. Insects are common at some hot springs and include spiders, beetles, and flies. Adult and larval *Ephydrya* spp., for example, feed on microbial mats in hot spring effluent (Figure 6h). Few vertebrates are restricted to thermal aquatic environments, but fish (*Alcolapia grahami*) inhabit hot spring pools with temperatures up to 46°C at Lake Magadi, Kenya (Figure 6i).

Environmental impact of terrestrial hydrothermal activity

The environmental consequences of terrestrial hydrothermal activity are highly diverse, as a few examples can illustrate. High concentrations of metals such as As that are present in effluent can be absorbed by vegetation in thermal areas with variable effects (Koch et al., 1999). High concentrations of fluoride in dilute hot-spring outflow are a problem (fluorosis) for animals and humans in parts of China, Kenya, Tanzania, and elsewhere (e.g., Xu et al., 1995). Toxins in thermophilic cyanobacterial mats have been blamed for deaths (e.g., Krienitz et al., 2003) of birds. Fumarole gases are commonly toxic and have killed animals and vegetation in many locations (e.g., Baxter et al., 1999). Effluent from geothermal sites can contaminate freshwater aquifers and surface waters. In many cases, the impact of hydrothermal activity is negative from a human perspective, but this is partly balanced by the strong appeal of hot springs, geysers, and fumaroles as tourist attractions.

Temporal and anthropogenic changes in hot spring and geyser activity

Hydrothermal features at the land surface are typically ephemeral, with activity lasting from months up to several hundred thousand years (see Chapter *Hydrothermal Environments, Fossil*), but renewed activity may recur at the same location following volcanic and tectonic events (e.g., faulting) or climate change. Hot springs, geysers, and fumaroles may continue to function provided the basic requirements of a heat source, reliable fluid source, and permeable fluid pathway to the surface are met. Variations in heat source typically occur over long timescales (e.g., magmatic cooling), but water supply and fluid pathways (permeability) to the land surface can vary over much shorter timescales and induce frequent and shorter-term changes in hydrothermal activity.

The fluid recharge is especially sensitive to climate. Sturchio et al. (1993), for example, showed that periods of sinter formation in the arid northern Kenya Rift during the Pleistocene could be correlated with phases of humid climate. Springs that discharged chloride waters and precipitated sinter when water tables were regionally high during wetter periods are now acidic fumaroles or have become extinct. Even very short-term climate changes can have an impact. The activity of geysers and hot springs on the shoreline of Lake Bogoria in Kenya, for example, responds rapidly to minor changes in lake level (<30 cm) that are induced by El Niño rains (Renaut et al., 2005).

Anthropogenic activity can also cause substantial changes to the level of the water table over periods of a few years, as examples from New Zealand demonstrate. Development of the Wairakei geothermal power plant in the late 1950s led to a large fall in the water table, subsidence, and the loss of at least 100 geysers (Glover, 1965; Bryan, 2008). Decreasing geyser activity and other

Hydrothermal Environments, Terrestrial, Figure 6 Life in terrestrial hydrothermal environments. (a) Vent of small geyser (former well bore) at Tokaanu, New Zealand. Despite the boiling water spray and overflow, a diverse microbial community inhabits the area at the vent and their remains are fossilized in the sinter. (b) Thick (up to 10 cm) microbial mats near the vent of a perpetually spouting, Na-HCO₃ hot spring at Lake Bogoria, Kenya (shown in Figure 2c). The mats (*Chloroflexus* and several cyanobacterial species) receive spray from the spring but are absent where water temperature is constantly >70°C. (c) Microbial mats (cyanobacteria) in shallow outflow (pH: 8.8; T: 40–85°C) from a Na-HCO₃ hot spring at Lake Bogoria, Kenya. (d), (e) Small coniform stromatolites, built by *Phormidium* growing in Kirihero spring pool (pH: 7.5; T: 38°C), Tokaanu, New Zealand. (i) *Alcolapia grahami* swimming in the vent pool (pH: 9.9; T: 46°C) of an alkaline hot spring, Lake Magadi, Kenya.

changes in the Whakarewarewa geothermal area over several decades have been attributed to natural changes in the subterranean plumbing system and to increased water extraction in nearby Rotorua.

The history of Geysir in Iceland is known from 1,294 AD because its behavior has been recorded in Icelandic literature. Historical sources show that the geyser activity has varied considerably, with periods of regular discharge alternating with periods of quiescence with eruptions. At Geysir, earthquakes rather than climate variability often seem to cause changes in its patterns of eruption (Torfason, 1985; Jones et al., 2007).

In some instances, changes in the subsurface aquifer and plumbing systems may trigger renewed activity after years of inactivity. The sudden, renewed activity of hot springs in residential areas can, for example, have a radical impact. This has happened recently (2000–2001) in Rotorua, New Zealand, where house owners awoke to find hot springs and mudpools in what used to be their back gardens, and a hydrothermal eruption (February 2001) sent mud 100 m into the air and created a pool 10 m in diameter in a local park.

Conclusions

Terrestrial hydrothermal environments occupy a small percentage of the Earth's surface but they provide a wealth of information on both geological and biological processes. These environments cover almost the entire spectrum of pH (0 to >10 in some alkaline hot springs) and water temperature range, and it is commonly possible to examine alkaline and highly acidic environments within a few kilometers of each other. For the geologists, they provide clues to mineral–water reactions occurring below the Earth's surface and the origin of some ore minerals. For the biologists, they provide opportunities to study a wide range of extremophiles in natural environments that, with care and permission, are generally accessible. With the discovery of possible siliceous hydrothermal deposits and highly acidic environments on Mars, the scientific interest in these environments is currently high and is likely to continue.

the ingestion of refractory organic carbon can lead to the excretion of more labile fecal pellets (Lee, 1992).

With most intrusive bioturbation, the sediment–water interface increases in surface area as a result of infaunal animal colonization. The larger (and deepened) sediment–water interface alters chemical fluxes between the sediment and water column. Animals that pump water through their burrow (bioirrigation) increase the rate of chemical flux. Most notably, irrigation of worm burrows with oxygenated seawater results in increased downward and lateral diffusion of O₂, which then affects the oxidation of redox-sensitive elements. For the aforementioned reasons, the accepted scheme of biogeochemical zones in sediment is an oversimplification. Bioturbation influences the solid phase and pore-water properties of sediment by increasing the transport of diagenetic reactants and products across the sediment–water interface. Consequently, surficial sediments cannot be considered a homogeneous medium characterized by one-dimensional vertical diffusion. They are, instead, heterogeneous and intensively mixed with a complex spatial distribution of biogeochemical zones that are difficult to accurately resolve (Aller, 1980).

Metal ion enrichment in ichnofossils

Cation enrichment in burrow linings is the result of sorptive processes. Metals concentrate in burrow linings in three ways: (1) adsorption, as oxide or oxyhydroxide coatings on to the high-energy surfaces provided by fine-grained particles (silt and clay); (2) as sulfide or phosphate phases under reducing conditions; or (3) associated with organic material (as adsorbed coatings or forming organo-metallic complexes) (Over, 1990). The relative importance of each type of enrichment mechanism varies with the depth of burrow penetration, the grain size/composition of the sediment, and bottom-water and pore-water composition.

Ichnofossils and cementation

Trace fossils commonly influence local cementation patterns by changing the sediment texture, its redistribution, and local composition (Gingras et al., 2004). They also facilitate the accumulation of microbial communities, and through their chemoheterotrophic metabolisms, the microbes can alter pore-water chemistry and saturation states. Ichnofossils also possess higher metal concentrations which can serve as nucleation sites for authigenic mineral formation. Although ichnofossils have been strongly linked to the distribution of microorganisms, there is no existing model associating trace fossil diagenesis to microorganic process.

Summary

The presence of ichnofossils/bioturbation in a sedimentary substrate has the effect of altering sediment distribution and permeability pathways. Moreover, the redistribution and stowage of organics in and around

ichnofossils strongly influence the distribution of microorganisms associated with the sedimentary surface. This has an impact on the nature and distribution of biochemical zonations in sediment. The mechanical and (bio)chemical nature of trace fossils influences diagenetic processes.

Definition

Immunolocalization: Technique using specific antibodies to localize macromolecules (proteins, polysaccharides) within biological material (subcellular fractions, cells, tissues, biofilms).

Introduction

Immunolocalization is based on the detection of specific targets (“antigens”; mostly proteins or polysaccharides) in biological samples (cells, tissue, biofilms) by antibodies

as probes. Regularly, antibodies of IgG subtype (Figure 1a) and IgM and IgA subtypes are used. The antibodies may be monoclonal (i.e., identical molecules that recognize only one epitope, which is a short stretch of amino acids or sugar molecules) or polyclonal (a set of antibodies directed against a mostly undefined variety of epitopes on the surface of a larger molecule or a cellular component). Specific non-covalent binding is brought about by the hypervariable region of the antibody (paratope), exactly fitting to an epitope. The hypervariable regions are the tip parts of the Y-shaped arm of the antibody (Figure 1a). All other parts, including the Fc-part, are structurally identical within one antibody subclass. Localization of the antigen is only possible when the specific (or primary) antibody ("probe") binds to a marker. A variety of antibody-marker systems are available for different applications (Figure 1b; see below). The marker may be coupled by different methods to the probe (Hoppert, 2003):

- By direct coupling of the marker to the probe prior to use in a localization experiment. The detection procedure requires just one binding step. The method is also termed *direct immunolocalization*.
- By binding of a secondary probe (mostly a secondary antibody) to the Fc-part of a primary antibody after this primary antibody is already bound to the specific target (two-step procedure). The secondary probe is coupled to the marker. The method is also termed *indirect immunolocalization*.
- By binding of tertiary probes to the secondary probe (for signal amplification). Tertiary probes are responsible for binding or deposition of the respective marker.

Immunolocalization in light and electron microscopy

For immunolocalization in (fluorescence) light microscopy, fluorescent dyes are used as markers

(immunofluorescence microscopy). The marker consists of the dye covalently coupled to a protein (e.g., the secondary antibody) that binds to the primary marker, the antigen-specific antibody. It is also possible to detect more than one target in a sample by the use of marker-probe systems with specificities for different targets coupled to fluorescence markers with discernable absorption–emission spectra. Access to the antigen in tissues or embedded samples can be achieved by (cryo-) sectioning or by permeabilization (Goldenthal et al., 1985). For (nonfluorescent) bright field microscopy, marker systems that catalyze enzymatic reactions are used, leading to deposition of dark-stained precipitates at the antigen binding sites (Ramos-Vara, 2005).

For electron microscopy, probes are coupled to colloidal gold as an electron dense marker. As stated for light microscopy, the marker can be directly coupled to the primary antibody, but regularly, a secondary system is combined with a primary antibody. Also, tertiary systems for signal amplifications are used. In equivalence to multiple detections of targets in light microscopy, it is possible to detect more than one target in a sample by use of marker-probe systems with discernable particle sizes of gold colloids. Particle sizes between 5 and 25 nm are used for experiments at the cellular level. Small gold particles may also be enlarged with silver or gold salt solutions for easier localization (Humbel et al., 1995). For epitope mapping in macromolecules, 1-nm markers ("nanogold") are available (Hainfeld and Powell, 2000).

Several modifications of the original immunogold marker technique can increase the resolution and sensitivity of the method. Dodecaborane clusters may be coupled to antibodies or Fab-fragments via polylysine dendrimers. The boronated antibodies have a lower detection limit in immunolocalization experiments than conventional gold conjugates. Detection of boron is performed by element-specific imaging in energy-filtering transmission electron

Immunolocalization, Figure 1 Antibody probes and colloidal gold markers: (a) Schematized structure of an IgG subtype antibody. (b) Primary antibody with bound secondary antibody and colloidal gold marker.

microscopes (Bendayan et al., 1989; Qualmann et al., 1996; Kessels et al., 1996).

Techniques like catalyzed reporter deposition ("CARD") use tertiary markers. CARD is a technique for amplification of a signal, originally designed for Western blotting, but modified for light and electron microscopy. In the first step, a specific primary antibody is coupled to the target. Then, in a second step, a secondary, biotin-tagged antibody is coupled to the primary antibody. A streptavidin–peroxidase conjugate is then bound to the biotin tag. Peroxidase catalyzes the deposition of tyramides indirectly. The tyramide itself is bound to a detectable marker (e.g., again biotin), and may be localized by the use of streptavidin-coupled colloidal gold for detection in the electron microscope (Mayer and Bendayan, 1997). For light microscopy, fluorescent dye-coupled tyramides are used (Wasielewski et al., 1997).

Related techniques

Besides the widely used antibodies, other specific probes for localization of a target may be used. Table 1 gives an overview of the relevant techniques. Lectin proteins have defined specificities to short carbohydrate stretches and are therefore an alternative to antibodies for detection of polysaccharides. They are mainly used for detection of glycosylated residues or polysaccharides on cell surfaces and/or in microbial biofilms (Kämper et al., 2004).

Especially when macromolecules are present in high concentrations, a target based on a substrate-specific enzyme may be applied. Enzyme–substrate interaction may also be detected with a substrate inducing the precipitation of an electron-dense marker to localize an enzyme activity.

Equivalent to in situ hybridization in light microscopy, the electron microscopic approach can allow high-resolution mapping of specific mRNA. The technique

Immunolocalization, Table 1 Techniques for the localization of biological macromolecules by light (LM) and electron microscopy (EM)

Problem	Specimen treatment	Marker system (technique; references)
Localization of specific proteins (antibody-gold/antibody-fluorescent probe) or carbohydrate complexes (lectin-gold/lectin-fluorescent probe) inside cells (LM/EM)	Ultrathin sections of resin-embedded samples subjected to immunolocalization	Antibody-colloidal gold, lectin-colloidal gold (Roth et al., 1980; Horisberger, 1985; Danguy et al., 1988)
Localization of specific proteins on the cell surface or on subcellular particles (EM)	Incubation of cells or subcellular fractions with the marker system prior to resin embedding or direct adsorption on specimen support films	Antibody-colloidal gold, lectin-colloidal gold (Acker, 1988; Rohde et al., 1988)
Localization of single protein epitopes and their relative position to each other on the surface of the object (EM)	Homogeneous protein preparations (especially large proteins or viruses) subjected to localization of epitopes	Antibody, Fab-fragment, (epitope-labeling; Hermann et al., 1991)
Detection of enzyme activities (EM)	Incubation of cells or subcellular fractions with the marker system	Specific enzyme substrate coupled to precipitation of electron dense marker (Hayat, 1973ff; Wohlrab and Gossrau, 1992)
Detection of macromolecular components acting as enzyme substrates (e.g., starch, lipids) (EM)	Labeling of enzyme substrates with gold particles coated with the relevant enzymes in ultrathin sections of samples	Enzyme-colloidal gold (Bendayan, 1985)
Localization of metabolites in the cell (EM)	Incubation of metabolically active cells with the precursor, embedding in conventional resin or by application of cryotechniques, treatment with a specific photoemulsion	Metabolic precursors (e.g., sugars or aminoacids) labeled with radioactive markers (autoradiography; Gregg and Reznik-Schüller, 1984)
Localization of specific DNA or RNA (preferably mRNA) sequences in cells (LM/EM)	Fluorescent in situ hybridization for light microscopy, hybridisation of DNA/RNA of fixed samples with the marker system followed by embedding and sectioning, detection of the marker system by autoradiography or with streptavidin-colloidal gold for electron microscopy	RNA or DNA oligonucleotide labeled with different markers (in situ hybridization; Amann et al., 1995; Egger et al., 1994)
Comparison of immunolocalization targets from overview (low resolution) to subcellular structures (high resolution) (EM)	Ultrathin (and semithin) sections of resin-embedded samples subjected to immunolocalization	Antibody-colloidal gold and antibody-fluorescent probe, lectin-colloidal gold and lectin-fluorescent probe (Takizawa and Robinson, 2003).

may be combined with specific signal enhancement methods (CARD, see above) and is suitable for high-resolution in situ hybridization (Cheung et al., 1999).

For microautoradiography, radiolabeled markers, incorporated into cell structures, are located by exposure to photographic emulsion. The deposition of silver bromide grains on the photoemulsion is detectable by light and electron microscopy. The technique is demanding and difficult to reproduce, though it gives information on processing and distribution of metabolites that cannot be obtained, on a structural level, by other methods (Gregg and Reznik-Schüller, 1984).

Correlative microscopy

The technique of correlative light/electron microscopy allows examination of the same sample at micrometer scale for overview images and at nanometer scale for imaging of features at high resolution. Regularly, (fluorescence) light microscopy and electron microscopy of samples is combined. The marker/probe systems are either suitable for both microscopic techniques at the same time or for combinations of different systems that are detectable either by light or by electron microscopy.

Quantum dots (qdots) are colloidal semiconductor nanocrystals and are detectable in the electron microscope, either as electron dense particles or via element specific imaging. Since qdots exhibit specific absorption/emission spectra in the light, they are also detectable as fluorescent markers. When qdots are coupled to primary antibodies, they are marker-probe systems suitable for both imaging techniques (Nisman et al., 2004).

Though it is possible to visualize ultrathin sections by (fluorescence) light microscopy, sections of several micrometer in thickness (semithin sections) are regularly more suitable. It is possible to obtain nearly identical features of a specimen when one ultrathin and one semithin is

consecutively cut from a specimen. Semithin and ultrathin sections are then processed in different ways, either with marker-probe-systems for immunofluorescence or for immunoelectron microscopy (Figure 2; Takizawa and Robinson, 2003; Wrede et al., 2008).

Correlation of data from immunolocalization may also be performed with other microscopic techniques, such as Raman microscopy, scanning electron microscopy, or atomic force microscopy.

Conclusions

It has already been understood in the first half of the past century that, besides comprehending biochemical or molecular reactions in organisms, the understanding of their organization is of equal importance (Hopkins, 1933). Tools for understanding organization of these processes have been developed consecutively, when methods became available to keep organisms alive or at least well-preserved down to molecular scale. The techniques revealed that the presumption of some early biochemists was right, i.e., metabolic pathways, growth and cell division, even of apparently non-compartmented bacteria, are organized in high ordered, large macromolecular complexes. Future direction of localization techniques will include the application of marker systems for high resolving microscopy systems that will allow observation of living cells down to nanometer scale (Donnert et al., 2006).

IRON SULFIDE FORMATION

Jürgen Schieber
Indiana University, Bloomington, IN, USA

Definition

There has been a great deal of research into the formation of sedimentary iron sulfide minerals because their history is intertwined with the biogeochemical cycles of iron, sulfur, carbon, and oxygen (Berner, 2001). Iron sulfides occur in sediments from a wide range of depositional environments, from the deep sea to the nonmarine, and the principal mineral in the rock record is pyrite (FeS₂, cubic). Its dimorph marcasite (orthorhombic) is considered metastable and apt to invert to pyrite over geologic time (Murowchick, 1992), but is probably more widespread than commonly acknowledged (Schieber, 2007). Presumed precursor minerals of sedimentary pyrite are mackinawite (FeS_{1-x}) and greigite (Fe₃S₄), minerals that impart a black coloration to modern reducing sediments (Goldhaber and Kaplan, 1974). Both are metastable and transform over time into pyrite or a mixture of pyrite and pyrrhotite (Berner, 1967). Pyrrhotite, hexagonal FeS, is thermodynamically stable in sediments (Berner, 1967), but extremely rare in modern or ancient sediments (Kobayashi and Nomura, 1972) due to kinetic limitations (Canfield and Raiswell, 1991).

Mackinawite and greigite are also known as acid-volatile iron sulfides (AVS) because in contrast to pyrite and marcasite they are readily soluble in HCl. Mineralogically, greigite is the sulfur analog of magnetite and is indeed strongly ferromagnetic (Dekkers and Schoonen, 1996). It can be formed by magnetotactic bacteria and dominates the magnetic properties of some modern sediments and

ARSENIC

John F. Stolz¹, Ronald S. Oremland²

¹Duquesne University, Pittsburgh, PA, USA

²United States Geological Survey, Menlo Park, CA, USA

Definition

Arsenic, element 33, is a metalloid in row VB of the periodic table. The main oxidation states are arsine (−3) elemental As(0), arsenite (+3), and arsenate (+5). Arsenate, As(V), and arsenite, As(III), are most common, with HAsO_4^{2-} and $\text{H}_2\text{AsO}_4^{1-}$ predominating under oxic conditions and H_3AsO^0 and $\text{H}_2\text{AsO}_3^{2-}$ prevalent in anoxic environments. Arsenic is found in minerals such as arsenosulfides (e.g., arsenopyrite, realgar), iron hydroxides and aluminosilicates (e.g., clays), fossil fuels, geothermal sources, and weathered volcanic and evaporitic deposits. Anthropogenic inputs may also be considerable as organoarsenicals such as roxarsone (3-nitro-4-hydroxy benzene arsonic acid) and monosodium and disodium methyl arsonate continue to see wide spread use. The toxicology of arsenic is well known; As(V) is an analog of phosphate and can disrupt oxidative phosphorylation, while As(III) binds to sulfhydryl groups and can inhibit respiratory enzymes. Nevertheless, arsenic is readily metabolized by microorganisms, undergoing redox reactions involved in resistance or energy generation. Organarsenicals are used for energy generation or as a carbon source. Environments with elevated concentrations can support a diverse arsenic metabolizing microbial community and a robust biogeochemical cycle (Oremland and Stolz, 2003).

As(III)-oxidizing prokaryotes are found among the alpha-, beta-, and gamma-proteobacteria, Deinocci (i.e., *Thermus*), and Crenarchaeota. Physiologically diverse, they include heterotrophic and chemolithoautotrophic species. The oxidation of arsenite involves the arsenite oxidase (AoxAB or AroBA), a member of the molybdenum family of enzymes. The gene sequence of the catalytic subunit (*aoxB* or *aroA*) is highly conserved, and oligonucleotide primers have been used to investigate the occurrence and distribution of As(III)-oxidizing

species. The dissimilatory reduction of As(V) has been demonstrated in Crenarchaeota, thermophilic bacteria, gamma-, delta-, and epsilon-proteobacteria, and low and high mole %GC gram positive bacteria. The enzyme, ArrAB, is also a molybdoenzyme, but differs significantly from AoxBA. The *arrA* gene has also been used as an environmental probe. Arsenic resistance involves a completely different type of arsenate reductase (ArsC, ACR2). Three different but comparable resistance systems (e.g., *E. coli*, *Staphylococcus*, *Saccharomyces*) have been described. ArsC catalyzes the reduction of arsenate to arsenite, while an arsenite-specific efflux pump (ArsB, ACR3) expels As(III) from the cell. Additional components include an ATPase (ArsA) and regulatory elements (ArsR, ArsD). Far less is known about arsenic methylation and demethylation, however, a SAM-dependent methylase has recently been described (Stolz et al., 2006).

Different microbially mediated processes can result in arsenic contaminated aquifers including (1) the oxidation of arsenic-containing pyrites, (2) the release of As(V) from reduction of iron oxides by autochthonous organic matter, (3) the reduction of iron oxides by allochthonous organic matter from dissolved organics in recharging waters, (4) the exchange of adsorbed As(V) with fertilizer phosphates, and (5) recharge with water contaminated with inorganic arsenic derived from the application or production of wood preservatives, pesticides (e.g., calcium arsenate), and organoarsenicals (e.g., roxarsone). Thus organisms that metabolize arsenic can impact the speciation, mobility, and toxicity of arsenic in the environment (Oremland and Stolz, 2005).

ASTEROID AND COMET IMPACTS

Charles S. Cockell

Definition

The impact of an extraterrestrial object (either an asteroid or comet) with the Earth's surface.

Introduction

There are now over 170 asteroid and comet impact craters that have been identified on the surface of the Earth (Table 1). These craters represent a small subset of the total impacts that have occurred during the history of life. Today, impact craters probably represent something on the order of 50,000 km² of Earth's surface. Although this is a small habitat area, impacts are the only extraterrestrial mechanism capable of causing localized ecological disturbance. Because impacts are a mechanism capable of delivering a pulse of energy into ecosystems, from a geobiological point of view they present an important addition to the overall picture of how ecosystems are disturbed and how they recover through time. Comparison to other processes involving ecological disturbance and recovery including volcanism, glaciation/deglaciation, storm damage, fire, landslides, and coastal erosion allows for a more complete picture of the role of catastrophic change in shaping the geobiology of the Earth.

Effects of impacts on the local environment

The kinetic energy associated with the collision of an asteroid or comet with the Earth is enormous. The collision of a rock with a 10-km diameter could release the equivalent energy of 10 million tonnes of TNT. An event on such a scale is expected to occur, on average, once in every 100 million years, and may be capable of causing global-scale disruption and extinction. Such an event is implicated in the Cretaceous–Paleogene extinctions. It is perhaps not surprising, therefore, that the biological destructiveness of impact events has overwhelmingly influenced our view of these objects and their role in ecological and evolutionary processes. However, it is important to realize that the great majority of impacts only cause effects at the local scale, although they may distribute material from the point of impact over wide areas. This contribution will focus on the local geobiological effects of impacts.

The impact of an asteroid and comet with the surface of the Earth has two profound effects that are relevant for life. First, the impact delivers energy into the target area with important geological consequences and second, it rearranges the hydrologic cycle, with implications for the availability of liquid water. Temperatures generated in

the impact cratering process can exceed several thousand degrees centigrade (Melosh, 1989). Most biologically important macronutrients volatilize at temperatures much lower than those associated with temperatures generated in the crater during impact (e.g., nitrates, 200°C; organic phosphorus, 350°C; inorganic phosphorus, 750°C; sulphur, 450°C; potassium, 570°C; and sodium, 880°C). In some parts of the crater, the substrate will not only be sterilized (made devoid of life), but will also be rendered oligotrophic (i.e., lacking in nutrients). The process and/or the extent of recolonization on melted and shocked substrates might be very different to that taking place on unprocessed substrate either inside or outside the crater and it might be very different from that associated with other agents of local ecological disturbance.

Recovery from impacts

Following the impact, there will be a well-defined sequence of biological recovery within the crater (Cockell and Lee, 2002). As there has been no large scale impact event in recorded human history, there has been no opportunity to observe these changes directly unlike post-volcanic recovery. However, observations on the present-day colonization of impact craters, which are in various states of preservation, can yield insights into the likely sequence of events (Cockell and Lee, 2002) and particularly the long-term influence of impacts on the geobiology of a region. Some general phases can be identified that are likely to occur. Following impact, the thermal pulse delivered by the impactor will heat the surrounding rock. High-temperature hydrothermal fluids generated in the modified thermal environment (Osinski et al., 2001) may, in the early stages following impact, provide a habitat for thermophilic and hyperthermophilic (heat-loving) microorganisms. For example, in the Houghton impact structure, a 24-km diameter structure on Devon Island in the Canadian High Arctic, the hydrothermal system may have lasted for at least 10,000 years. The crater cavity formed during the impact acts as a hydrologic depression and will provide a new habitat for aquatic life (either freshwater on land or marine if the impact occurred in the ocean and excavated a new salt-water filled environment).

Following impact, intracrater lacustrine ecosystems become established, depending upon the size of the structure. Even today, many ancient impact craters support lakes. The biota associated with impact crater lakes has now been studied in several cases. For example, the low biomass and poor diversity of the 3.4-km-diameter New Quebec Crater in Canada and the 18-km-diameter El'gygytyn crater in Siberia (Gronlund et al., 1990; Cremer and Wagner, 2003), contrast with the rich, abundant bacterial and algal ecosystem associated with the 1-km-diameter Tswaing impact crater in South Africa (Ashton and Schoeman, 1983; Schoeman and Ashton, 1982) (Figure 1). The Tswaing crater is situated in South African bushveld and receives organic input from the rich

Asteroid and Comet Impacts, Table 1 Information on the craters discussed in this article

Name of crater	Country	Size of crater (km)	Age of crater (Myr)
Chesapeake	Virginia, USA	90	35.5 ± 0.3
El'gygytyn	Russia	18	3.5 ± 0.5
Houghton	Canada	24	39.0
Lockne	Sweden	7.5	455
Mjølner	Norway	40	142.0 ± 2.6
New Quebec	Quebec, Canada	3.44	1.4 ± 0.1
Ries	Germany	24	15.1 ± 0.1
Tswaing	South Africa	1.13	0.22 ± 0.05

Asteroid and Comet Impacts, Figure 1 Impact crater lakes. Two examples of lakes formed in the cavity excavated by two impact events. El'gygytgyn in Siberia (left) and New Quebec in Canada (right).

vegetation that grows within the impact crater cavity. The area is characterized by erratic rainfall (between 400 and 750 mm a year) and summer temperatures that vary between a mean minimum and maximum of 14.2 and 35.2°C, respectively. The New Quebec crater is in a cold environment; temperatures are relatively constant at approximately 2.5–3°C down to the bottom (267 m) of the lake. Although the biota that takes advantage of an intra-crater lake will be influenced by the local climatic regimen, these examples show how impact excavation provides benefits for life by forming a cavity, in which water collects.

Once the crater begins to cool, exposed melt rocks can provide a substrate for primary succession (Cockell et al., 2001). The drainage of the lake by the breach of the crater wall will expose impact lithologies which then provide a substrate on which colonization can occur. Thus the sequence of geobiological events that occur after impact will be influenced by the general characteristics of impact craters (e.g., presence of a thermal pulse, an impact cavity) and the specifics of any given crater (e.g., duration of thermal pulse, local climate, size and depth of intracrater lake, substrate into which impact occurs, and the scale of the impact).

Ultimately a crater will become buried or eroded to point where the internal ecology may be indistinguishable from the exterior ecology.

As three-quarters of the Earth is ocean, most impacts occur in water and one initial effect is the large-scale movement of water bodies. Investigations of strata in a corehole 30 km northeast of the Mjølnir crater, formed in the late Jurassic by the impact of an object into the 300–400-m deep paleo-Barents Sea, suggest that the impact event mixed water masses and caused a large introduction of nutrients into the Sea (Smelror et al., 2002). High concentrations of marine algae suggest that the increase in the availability of ammonia, nitrates, phosphates, and iron contributed to a postimpact bloom. The backwash of a tsunami, caused by the impact, is postulated

to be the reason for the high concentrations of freshwater algae in the strata. The mixing of the water, caused directly by impact, would also have been exacerbated by the collapse of the crater after formation.

Geomicrobiological influence of impacts

In the sense that impacts merely create a “hole in the ground,” their aquatic ecosystems may be indistinguishable from any topographic low in a similar location. However, it is evident that asteroid and comet impacts can have an important influence on the target lithology that is quite specific to impact and can alter the habitat for rock-dwelling microorganisms, making impact craters an important site for geomicrobiological investigations (Cockell et al., 2002). The temperatures and pressures of impact commonly increase the fracture space within rocks, which provide a greater abundance of habitats for endoliths, i.e., organisms which inhabit cracks within rocks. In some instances, the increase in permeable space within the target material in combination with an increase in the translucence of the rock in the visible part of the spectrum can yield new habitats suitable for phototrophs. Impact-shocked Precambrian gneiss in the Haughton crater has been shown to preferentially offer cryptoendolithic habitats for photosynthetic cyanobacterial colonists (Figure 2). The rock is not otherwise a suitable habitat for them (Cockell et al., 2002). This finding constituted empirical evidence for the formation of a microbial habitat specifically by an asteroid or comet impact.

The fate of highly porous substrates versus low porosity substrates during impact is different (Kieffer, 1971). In the former case more of the impact energy must be taken up in pore collapse. Thus, an examination of the effects of asteroid and comet impacts on the colonization of porous sedimentary target lithologies can provide a model with which to understand more generally the effects of impacts on the colonization potential of rocks (Cockell et al., 2005). In a study of impact-shocked sandstones from the

Asteroid and Comet Impacts, Figure 2 Cyanobacterial communities living in impact-shocked gneiss from the Houghton impact crater, Devon Island, Canadian High Arctic (left) and within class 3 shocked sandstones from the same crater (right). Scale bars 1 cm.

Houghton impact structure, Canadian High Arctic, it was shown that shock pressures from 0 to ~ 10 GPa caused the pore structure to collapse, thus rendering the material less amenable to microbial colonization. However, as shock pressures are increased to ~ 50 GPa the material becomes successively better for colonization on account of the formation of vesicular regions in the rock from rock fracturing and melting, improving conditions for colonization. At higher shock pressures colonization potential is again decreased as a solid glass is formed which is impermeable, although potentially still accessible to rock-boring microorganisms.

Thus, in summary, we can say that in general impact events may have the effect of turning lithic habitats on their head. Habitats that were previously impermeable become better sites for colonization as the rocks are fractured. Habitats that were good sites for colonization are rendered less permeable because of pore collapse, although, as the sandstones of Houghton illustrate, the effects on any given lithology tend to be complex.

Within and around impact craters new minerals can be generated in hydrothermal systems that later become habitats for life. Gypsum deposits laid down in the Houghton crater have become a habitat for cyanobacteria which inhabit the inter-sheet spaces between the sulphate crystals (Parnell et al., 2004). The extent to which these organisms are active is uncertain, but they must certainly be halotolerant.

During impact, the target lithology, especially if it is stratified and diverse, will be fragmented and mixed, leading to a heterogeneous substrate in which diverse geochemical sources of nutrients are brought into close proximity. A study of the weathering of a tsunami surge deposit in the Lockne impact crater in Sweden (formed ~ 455 million years ago) showed how lichens preferentially first colonized the soft chlorite clasts incorporated into the impactite (Cockell et al., 2007). The dissolution of the calcium carbonate clasts by fungi and other

organisms creates cavities in the rock, enhancing weathering and causing the rock to exfoliate in sheets. Previous studies on the chemical weathering of impact-shocked rocks from the Ries crater, Germany, showed that the deformation features introduced into quartz were sites of preferential weathering (Leroux, 2005). Diverse impact-generated lithologies can be used as a model to understand microbial weathering of other mixed sedimentary lithologies such as greywackes and microbe–mineral interactions in extremely disturbed geological settings in general.

Most of the geobiological studies conducted to date pertain to the surface environment. The first drill core retrieved from an impact crater with robust microbiological contamination control came from the Chesapeake Bay Impact Crater and was retrieved during the ICDP (International Continental Drilling Project)-USGS (United States Geological Survey) deep drilling project in 2005 (Gohn et al., 2008). A core of length 1.8 km was retrieved. The sequence included a 600 m sequence of postimpact sediments laid down since the impact in the late Eocene and 1.2 km of postimpact tsunami and “fall-back” deposits laid down in the crater cavity immediately after impact. This work has shown that the microbial diversity and abundance of microorganisms correlates to the lithologies in the crater cavity, showing that impacts can significantly disrupt the characteristics of the deep biosphere.

Impact events and astrobiology

The study of the geomicrobiology of impact craters provides useful clues to the opportunities for life on the Archean Earth since the emergence of life ~ 3.5 Gya ago, when the impact flux were higher than today. The formation of hydrothermal systems and the fracturing of rocks are two such opportunities that impact craters might have offered to early life. Insofar as asteroid and comet

impacts are universal (in that no solar system-forming process is known that is completely free from remnant material), habitats created in craters yield insights into the possible habitats for life on other planets, such as Mars. In particular, the likelihood that impacts melt permafrost, or generate deep fracturing into regions of a planet where liquid water is available, suggests that they offer intriguing possibilities as sites to examine the potential habitability of Mars, past and present.

Summary

Asteroid and comet impacts can cause global environmental perturbations through gross changes in atmospheric chemistry. However, much more commonly they alter geobiology at local scales. Through local disruptions of hydrology and geology, they generate new habitats and substrates, the most conspicuous being intracrater lakes. The energy delivered during impacts can also change habitats at the micron scale through changes in target lithology creating entirely novel geomicrobiological environments which, through pressure and temperature effects, are distinguishable from volcanic and other disturbed environments. The geobiological study of asteroid and comet impacts completes our picture of the role of catastrophic disturbance in influencing life on Earth alongside terrestrially mediated mechanisms of environmental change.

Definition

Astrobiology is the interdisciplinary science that studies the origin, evolution, distribution, and future of life in the Universe. It is a highly interdisciplinary field that engages many scientific disciplines, including biology, biogeochemistry, paleontology, earth and atmospheric sciences, planetology, and astrophysics among others.

Historical perspective

Astrobiology as a term was first coined in the 1940s to encompass early scientific ideas about how to explore for extraterrestrial life (Dick and Strick, 2004). During the 1960s, astrobiological research was focused more

IRON SULFIDE FORMATION

Jürgen Schieber
 Indiana University, Bloomington, IN, USA

Definition

There has been a great deal of research into the formation of sedimentary iron sulfide minerals because their history is intertwined with the biogeochemical cycles of iron, sulfur, carbon, and oxygen (Berner, 2001). Iron sulfides occur in sediments from a wide range of depositional environments, from the deep sea to the nonmarine, and the principal mineral in the rock record is pyrite (FeS₂, cubic). Its dimorph marcasite (orthorhombic) is considered metastable and apt to invert to pyrite over geologic time (Murowchick, 1992), but is probably more widespread than commonly acknowledged (Schieber, 2007). Presumed precursor minerals of sedimentary pyrite are mackinawite (FeS_{1-x}) and greigite (Fe₃S₄), minerals that impart a black coloration to modern reducing sediments (Goldhaber and Kaplan, 1974). Both are metastable and transform over time into pyrite or a mixture of pyrite and pyrrhotite (Berner, 1967). Pyrrhotite, hexagonal FeS, is thermodynamically stable in sediments (Berner, 1967), but extremely rare in modern or ancient sediments (Kobayashi and Nomura, 1972) due to kinetic limitations (Canfield and Raiswell, 1991).

Mackinawite and greigite are also known as acid-volatile iron sulfides (AVS) because in contrast to pyrite and marcasite they are readily soluble in HCl. Mineralogically, greigite is the sulfur analog of magnetite and is indeed strongly ferromagnetic (Dekkers and Schoonen, 1996). It can be formed by magnetotactic bacteria and dominates the magnetic properties of some modern sediments and

even some ancient sedimentary rocks (e.g., Krs et al., 1990).

Although they also occur in nonmarine sediments, the bulk of sedimentary iron sulfides forms in marine sediments during early diagenesis via microbial reduction of seawater sulfate. The general process of their formation has been elucidated by a number of classical studies (e.g., Kaplan et al., 1963; Berner, 1970, 1984). From a geobiological perspective, iron sulfides are of interest as their presence denotes anoxic and reducing pore waters, because they can preserve minute details of soft tissues (e.g., Briggs et al., 1991; Gabbott et al., 2004; Kammer and Ausich, 2007), because microbial life in pore spaces may be entombed in growing iron sulfide grains (Schieber, 2002a), and because the iron sulfide matrix is apparently able to preserve more complex organic molecules (such as amino acids) for long geologic time periods (Nardi et al., 1994). For an in-depth discussion of sedimentary sulfide formation and the linkage to the global sulfur cycle the reader is referred to an excellent overview by Goldhaber (2003) in the Treatise on Geochemistry.

Pathways to sedimentary iron sulfides

The understanding of iron sulfide formation under Earth surface conditions has largely been informed by extensive laboratory studies (see summary by Morse et al., 1987). Multiple potential pathways for sedimentary iron sulfide (pyrite) formation have been recognized. As summarized by Goldhaber (2003), these include (1) direct precipitation of pyrite from polysulfide bearing solutions, (2) progressive conversion of solid iron monosulfides to pyrite (Figure 1) by polysulfides, (3) reaction of H_2S with a solid iron monosulfide to form pyrite (release of H_2 gas), and (4) reactions that involve iron loss from a solid iron monosulfide precursor through oxidation.

As indicated by this summation, the body of published literature lives by the assumption that iron monosulfides (generic for mackinawite and/or greigite) are necessary precursors for pyrite formation in sediments. Thus, the normal iron sulfide paragenesis in sediments is presumed to proceed from mackinawite over greigite to pyrite (e.g., Wilkin and Barnes, 1996; Benning et al., 2000). The tacit assumption is that sedimentary pyrite cannot form in the absence of acid-volatile iron monosulfides (AVS). Yet, direct evidence for this traditional view is scant. Rickard and Morse (2005) have argued strongly that in numerous studies of modern sedimentary pyrite formation abundant pyrite is produced in the absence of detectable AVS. They argue that many of the equations that describe sedimentary pyrite formation in the literature represent net mass balances and do not describe the actual reaction processes. Rickard and Morse (2005) point out that AVS are not required for reaction pathways that involve polysulfide or H_2S (numbers (2) and (3) from above), and that aqueous FeS clusters could be involved instead of solid monosulfide phases. They propose that the products of the diagenetic sulfide machinery,

Iron Sulfide Formation, Figure 1 SEM photomicrograph of pyrite framboids from modern reducing muds of the Santa Barbara Basin, offshore southern California. The sediment was cored, stabilized in Spurr resin, and polished with diamond paste. At lower right a similar well-formed framboid might be found in ancient mudstones. In the center a less ordered framboid with bright grains that are pyrite (EDS analysis), and gray grains that have about half the sulfur peak intensity (EDS spectra) of typical pyrite grains. The interpretation is that the gray grains are the Fe-monosulfide precursor material (amorphous FeS , mackinawite, ~greigite) that has been the subject of geochemical studies. (Berner, 1970; Sweeney and Kaplan, 1973; Goldhaber and Kaplan, 1974; Murowchick and Barnes, 1987; Wilkin and Barnes, 1997.)

mackinawite, greigite, and pyrite, may form either simultaneously or in no particular order during sediment diagenesis.

The building blocks

Regardless of how sedimentary iron sulfides are ultimately produced, it is instructive to examine where the requisite iron and sulfur come from. Because iron is insoluble in the presence of oxygen, the iron content of sea water and freshwater is extremely low (Stumm and Morgan, 1996). It is, therefore, practical to assume that any iron that is available for iron sulfide formation has to be part of the particulate matter that makes up the sediment. Typical deltaic and marine muds have iron contents that range from 4% to 8% (Calvert, 1976; Chester and Asten, 1976; Aller et al., 1986), but not all of that iron is equally available for diagenetic iron sulfide formation. Although there may be plenty of iron in iron silicates (e.g., biotite, chlorite), release of that iron requires alteration/destruction of the containing silicate, a process that operates more efficiently under the higher temperatures of deep burial diagenesis (Figure 2). Thus, this iron fraction is not available during early diagenesis when the bulk of sedimentary iron sulfides is formed.

Iron Sulfide Formation, Figure 2 SEM photomicrograph of late diagenetic biotite alteration associated with pyrite formation (backscatter (BS) image) in the Devonian Ohio Shale, Kentucky, USA. Pyrite (very bright) forms along cleavage planes near the end of a biotite flake because during alteration these are the places where iron is released. The surrounding pore waters must have contained abundant H_2S . Iron was precipitated as FeS_2 very close to the place where it was released from the biotite lattice, and it was not able to migrate away from its source grain.

The iron fraction that is critical in early diagenesis is in the form of coatings of iron oxyhydroxides on detrital grains (especially on clays; Carroll, 1958), as well as in the form of particulate/colloidal iron oxyhydroxides (e.g., Allard et al., 2004). Of the 4–8% of total iron that we can expect in average muddy sediments, only some 10%, and under very favorable circumstances up to about half, is made available by reducing agents (Gibbs, 1977; Trefrey and Presley, 1982; Canfield, 1989) for the formation of early diagenetic iron sulfides.

Sulfur, of course, is readily available via seawater sulfate in marine sediments, and for surficial sediments the overlying seawater represents an essentially limitless reservoir. Only upon burial, once consumed sulfate can no longer be replenished by downward diffusion, does sulfur become a limiting commodity. In all sediments, the production of H_2S for sulfide formation is accomplished by sulfate reducing prokaryotes that utilize sulfate as an electron acceptor for energy producing chemical reactions. For carbohydrate oxidation this reaction may be written as

Thus, organic matter that can be utilized by sulfate reducing microbes is essential for the operation of the sedimentary sulfide factory. Even in the presence of abundant sulfate, sulfide production will only occur if there is “food” for the microbes. Sulfate reduction equations proposed by Canfield and Raiswell (1991) suggest that it will require about 5 cm^3 of microbially “digestible” organic matter (e.g., lactate, ethanol, acetate, sugar) to precipitate 1 cm^3 of FeS_2 . Thus, low organic matter contents in sediments will tend to limit sulfide production and the amount of iron that can be converted to pyrite.

Above considerations also have implications with regard to where we most likely will find large quantities of iron sulfides in sedimentary rocks. Because pure carbonates typically accumulate far from the influence of terrigenous clastics, the average carbonate rock tends to contain only minor quantities of iron and thus, sedimentary iron sulfides are generally low in abundance. Sandstones, even though they may contain appreciable quantities of iron in the form of iron bearing detrital silicates and as iron oxyhydroxide grain coatings, are comparatively poor in organic matter and thus lack the fuel to drive extensive early diagenetic sulfate reduction. When we do find substantial accumulations of iron sulfides in carbonates or sandstones, they are in the majority of cases due to late diagenetic processes that benefited from higher temperatures and constituent bearing formation waters. Exceptions occur when carbonates or sandstones are interbedded with shales and mudstones, because the latter carry the bulk of iron in the sedimentary mass balance (Taylor and McLennan, 1985). The lion’s share of sedimentary iron sulfides is therefore contained in fine grained terrigenous rocks (shales and mudstones).

Iron sulfide textures

Pyrite, the most commonly reported iron sulfide in sediments, is cubic in structure, and thus cubes and octahedra are common morphologies. In addition to these fundamental forms, iron sulfides are also patterned into a wide range of textural types (e.g., single grains, framboids, pore fill cements, concretions, pyrite cemented layers, and pyritic lags) that carry useful information about conditions during deposition and early diagenesis. From a geobiological perspective, concretionary iron sulfide accumulations are of particular interest because their formation was likely driven by decomposing organic matter. Their morphology varies widely, and many types have been described, such as pyritized burrow tubes, infilling and encrustation of fossils, replacement of fossil hard parts (carbonate shells, bones), and pyritization of soft tissues.

Single grains

As single grains, pyrite may occur as a disseminated component, ranging from less than $1 \mu\text{m}$ to tens of micrometer in size. Yet, while these may indeed be grains that record a single growth episode, etching (e.g., with HNO_3) may reveal internal textures that speak to multistage growth.

Pyrite framboids

Ubiquitous in modern and ancient sediments, pyrite framboids are typically near-spherical in shape, range in diameter from about $1 \mu\text{m}$ to tens of micrometers, and are themselves composed of tiny, discrete, and equigranular pyrite crystallites. They have been the subject of numerous studies, and early on there was an assumption that organic matter (Figure 3) somehow plays a role in their formation (Schneiderhöhn, 1923; Love,

Iron Sulfide Formation, Figure 3 SEM photomicrograph of an etched pyrite framboid in the Devonian Chattanooga Shale of Tennessee, USA. The etching with HNO_3 removed the pyrite crystallites and left behind a honeycomb of organic matter that filled the space between the pyrite grains. The organic matter has the same composition as the unstructured kerogen in the surrounding sample.

1967). Yet, because they can also be produced abiotically in the laboratory (Berner, 1969; Sweeney and Kaplan, 1973), the role of organic matter remains a matter of debate (e.g., Kalliokoski, 1974). The abundantly noted close association of pyrite framboids and organic matter may well be coincidental because the reducing conditions that promote their formation are best developed in sediments with elevated contents of organic matter.

Most pyrite framboids observed in sedimentary rocks consist of microcrysts (Figure 4a; typically cubes, octahedral, or pyritohedra) that show poorly defined to highly ordered packing into spherical aggregates (Wilkin and Barnes, 1997; Ohfuji et al., 2005). The size ratio of microcrysts to framboid diameter is quite variable (Figure 4b). Directly adjacent framboids may show vast differences in diameter/microcryst size ratios (Figure 4b), and also show contrasting microcryst morphology. These textural details probably carry some information about the pore water environment during formation, but at present their significance is poorly understood. Pyrite framboids can survive intact into greenschist grade metamorphism, and can for example, identify slates that originated as marine shales (Figure 4d).

Iron Sulfide Formation, Figure 4 Pyrite framboids in the rock record. All images are SEM photomicrographs (backscatter mode). (a) Moderately well-ordered framboid from the late Devonian New Albany Shale (Indiana, USA). Note differential compaction of clays and organic matter around the framboid, indicating framboid formation prior to compaction when the sediment contained ~80% water. (b) Framboids in modern sediments from the Santa Barbara Basin (offshore southern California, USA). Note the strong differences in diameter/microcryst size ratios and the contrast in microcryst morphology (pyritohedra vs. complex cubes). (c) Framboid consisting mostly of variably sized octahedra (Ordovician Powers Steps Formation, Newfoundland). (d) Pyrite framboids that survived low-grade metamorphism and cleavage development ($\pm$ horizontal) in the Ordovician Martinsburg Slate of New Jersey, USA.

The formation processes of pyrite framboids are discussed at length by Wilkin and Barnes (1997), and further perspectives are presented by Ohfuji et al. (2003) and Butler and Rickard (2000). Fundamentally, in order to form framboids within the pore spaces of a sediment, iron should be able to migrate to the site of formation and thus, the pore waters have to be nonsulfidic (anoxic-nonsulfidic; Berner, 1981). Furthermore, in order for iron oxyhydroxides to dissolve in the pore waters, they also need to be free of oxygen. In the idealized sequence of microbial decay reactions in sediments (Brett and Allison, 1998; Curtis et al., 2000), this is known as the “suboxic” zone, and is followed by the “anoxic” zone of sulfate reduction. The boundary between the suboxic and the anoxic zone is also referred to as the redox interface, and it is here where dissolved iron meets sulfide and iron sulfides can precipitate. Pyrite framboids form in that region. Yet, whereas these zones are thought to be layered atop each other in surficial sediments, in reality it is a bit more complex. Every single framboid implies that iron migrated from a surrounding sediment volume to form this localized accumulation, and by default this means that there was a localized source of sulfide that via iron sulfide precipitation maintained the underlying concentration gradient. The sulfide source was probably a colony of sulfate reducing bacteria that prospered around a lump of easily digested organic matter. Thus, rather than simply being a narrow bedding-parallel zone in which dissolved iron interacts with dissolved sulfide, the realm of framboid formation (the redox interface) is heterogeneous. It makes more sense to think of it as “islands” of microbial sulfide production in a “sea” of iron-bearing pore waters (Figure 5), the reducing microenvironments that have been mentioned elsewhere in the literature (e.g., Hudson, 1982).

Whereas in typical sediments the redox interface is situated somewhat below the sediment water interface, there are situations where the redox interface is actually located in the overlying water column, such as in the Black Sea. In euxinic basins, with the lower portion of the water column being anoxic and sulfidic, framboids can grow in the water column near the redox interface and then settle and become part of the accumulating sediments (Wilkin et al., 1996). Wilkin et al. (1997) report that framboids of that origin are rather small (mean framboid diameters $<5\ \mu\text{m}$, narrow size distribution) when compared to those forming in sediments underlying oxic and dysoxic waters (mean framboid diameters $5\text{--}10\ \mu\text{m}$, broad size distribution). The implication of this is that one can use the framboid size distributions of sediments to determine whether they accumulated beneath an anoxic water column. Wignall and Newton (1998) applied this concept to ancient mudrocks and were able to correlate framboid size distributions with paleoecologically based reconstructions of bottom water oxygenation. However, framboid size in sediments may also be influenced by the availability of iron during early diagenesis. For example, a study of framboid size distributions in sediments from the Santa Barbara Basin (offshore southern California) indicates that framboid size distributions primarily reflect conditions within the immediate surface sediment (such as availability of readily soluble iron). Framboid size distributions in annual varves (1984–2004) from the Santa Barbara Basin suggest three euxinic interludes in the past 2 decades, even though seasonal bottom water surveys consistently recorded suboxic to dysoxic bottom water conditions (Schieber and Schimmelmann, 2006). It appears, therefore, that it may not be possible to draw conclusions about water column conditions from pyrite framboid size distributions.

Iron Sulfide Formation, Figure 5 SEM photomicrographs (backscatter mode) of localized pyrite framboid formation in reducing microenvironments of Santa Barbara Basin (offshore southern California) surface sediments. At left, a multichambered calcareous foraminifera with chambers filled by framboids. At right, a framboid filled diatom. Lower right half, imaged in secondary electron (SE) mode (framboids not visible). Upper left half, imaged in backscatter (BSE) mode, the framboids shine through the lower density opaline “lid.”

Polyframmboids

Pyrite frammboids may also occur as larger aggregates, so called polyframmboids. These have been described from sediments of various ages (Schieber and Baird, 2001) and have a tendency to form in cavities of organic remains (Figures 5 and 6). Judging from differential compaction around polyframmboids (Figure 6), they must form prior to any compaction, just like single pyrite frammboids. They also imply iron migration from a surrounding sediment volume that was anoxic but not sulfidic. The difference between polyframmboids and regular pyrite frammboids may simply be a higher iron supply from the pore waters, or alternatively that the “islands” of microbial sulfate reduction are more widely spaced and thus, focus the available iron onto fewer sites of precipitation. Because most marine sediments start out with comparable amounts of reactive iron, the latter scenario is more likely.

Small-scale pyrite aggregates and clusters

Pyrite bodies that consist of coalescing, irregular, rounded clots of small pyrite grains have been described as

aggregated pyrite by Hudson (1982). The cores of individual clots may be small pyrite crystals or pyrite frammboids, and these cores are overgrown by coarser pyrite crystals (Figure 7). In places these overgrown grains show a radiating bladed habit. These overgrown grains tend to form somewhat later in diagenesis, at a point when downward diffusion of seawater sulfate is increasingly restricted (Strauss and Schieber, 1990). This type of pyrite aggregate ranges in size from tens of microns to several millimeters.

Concretions and pyritic layers

Iron sulfide concretions in sediments vary in size from a few millimeters to more than 10 cm. Like other occurrences of sedimentary iron sulfides they are most commonly encountered in mudstones and typically occur in distinct nodule bearing horizons (Figure 13). Although pyrite is usually reported as the sole iron sulfide mineral, careful examination reveals many examples of inverted or extant marcasite within these iron sulfide accumulations (Schieber, 2002b, 2007; Schieber and Riciputi,

Iron Sulfide Formation, Figure 6 SEM photomicrographs of pyrite polyframmboids (backscatter images). Note differential compaction around polyframmboid aggregates. (a) Ordovician Powers Steps Formation, Newfoundland, Canada. Note “squeezing” of frammboids, suggesting initial formation in a confined space (transported?). (b) Devonian Chattanooga Shale, Tennessee, USA. Here, the polyframmboid is still enclosed (black line) in an algal cyst (Tasmanites) that formed the initial reducing microenvironment. The space between frammboids is filled with secondary, coarser pyrite cement.

Iron Sulfide Formation, Figure 7 SEM photomicrographs of pyrite aggregates (backscatter images). (a) Irregularly shaped aggregate consisting of smaller pyrite clots. (b) Small cluster of pyrite clots that still have visible frammboids in their cores. The overgrown pyrite has radiating habit and may have originated as marcasite.

2005). Especially the larger concretions approximate prolate ellipsoids (Figure 8a) and show differential compaction of the surrounding mudstone (Figure 13). These features attest to growth prior to substantial compaction and growth within a stratiform chemical zone (anoxic and nonsulfidic; Berner, 1981). In order for iron to be directed to localized sites of precipitation within this zone, there need to be sites of abundant H_2S production, as, for example, provided by microbial decay of buried organisms (e.g., bivalve, fish). Thus, the interiors of iron sulfide concretions are good targets for finding well-preserved fossils. In order to allow the concretions to grow to large size, this chemical zone has to remain stationary for a long time, probably on the order of thousands of years (Canfield and Raiswell, 1991). Not uncommonly, the iron sulfide concretions in a given layer also add up to a substantial excess of iron relative to the background sediment, suggestive of prior concentration by mechanical and chemical reworking (see Section “Marcasite and its implications”). Thus, horizons with abundant iron sulfide concretions or abundant pore filling iron sulfides imply very slow sedimentation at the time of nodule formation and should also alert us to the possibility of reworking and erosion of underlying sediments (Schieber and Riciputi, 2005). Other options for the formation of iron sulfide-enriched horizons are, for example, to cover iron-oxide rich layers with an organic-rich anoxic sediment drape (Ingri and Ponter, 1986). Migration of a sulfide-rich reduction front into the iron-bearing layer would effectively convert the iron oxides to pyrite.

Hydraulic concentrations (lags)

Because iron sulfide grains are of much higher density than associated silicates and organic matter, they are liable

to be concentrated into lag deposits when the easily eroded surface sediment is reworked by bottom currents and storms. Reworking can be manifest in the form of submillimeter concentrations of pyrite framboids (Figure 11c), as well as in decimeter thick concentrations of a wide variety of sedimentary pyrite grains (Figure 11). Examples are pyrite concretions (Figure 8), pyritized burrow tubes, and pyrite-filled algal cysts (Figure 6b). Lags that contain abundant iron sulfide grains have been described from the rock record in many places (e.g., Baird and Brett, 1991; Schieber, 1998a; Schieber and Baird, 2001). The mechanical enrichment of iron sulfides has two major implications and consequences. First, because of limitations on the initial soluble iron content of sediments, a substantial volume of sediment has to be sacrificed to erosion in order to concentrate all the iron into a single layer. Let us assume, for example, that typical mudstones have about 5% iron. A 5 cm thick lag with about 60% FeS_2 by volume would require that (at a minimum) a 50 cm thick (fully compacted) shale interval be winnowed to provide the necessary iron. Given that early in depositional history the uppermost meters of this shale (mud) had probably still an average porosity of at least 50%, the presence of this lag then implies that at least one meter, and more likely several meters, of sediment was removed.

Iron sulfides and fossil preservation

Replacement and encrustation of calcareous shells

Encrustation and replacement of calcareous shells by iron sulfides are widely observed in the rock record. Typically, an assumption is made that the iron sulfide in question is pyrite, but a case can be made wherein marcasite was involved at least initially (see below). One way to think about calcite/aragonite replacement is that the saturation

Iron Sulfide Formation, Figure 8 A collection of iron sulfide concretions. (a) Oblate concretion from the Devonian Ohio Shale of eastern Kentucky, USA. Probably contains marcasite around the periphery, just like that seen in Figure 13. (b) Discoid-flattened pyrite concretions from the Jurassic Posidonia Shale near Dotternhausen, Germany. These may originally have been marcasitic. (c) Heavily pyrite (plus marcasite?) encrusted ammonite from the Lower Jurassic (Amaltheenton) near Dotternhausen, Germany. The specimen weighs at least 5 kg (courtesy of Dr. M. Jäger, Holcim GmbH). Without pre-concentration of iron in the sediment, it would require all the iron contained in a volume of 250 l of sediment (80% water content, 5% Fe in dry matter) to be concentrated into this concretion. Because iron redistribution is not that efficient, it is more likely that something on the order of 1 m³ of sediment has to be depleted.

Iron Sulfide Formation, Figure 9 Fossil preservation by iron sulfides, SEM photomicrographs. (a) Chamber lining iron sulfides in an ammonite (secondary electron image), Lias delta (Amaltheenton) near Dotternhausen, Germany. The septa of the ammonite (*white arrows*) are now calcitic, and the chamber interior is filled with calcite as well. (b) Close-up of the iron sulfide (bright, backscatter image) encrusted septum. The encrusting sulfides are a mixture of pyrite (framboids) and marcasite (overgrowth). (c) Close-up of encrustation near septum (backscatter image). The marginal areas of the septum (marked between *white arrows*) have a different texture than the areas further away. The latter areas contain pyrite framboids (*black arrow*) in a coarser matrix of blocky to radiating crystals. (d) Close-up of framboids (*white arrows*) in coarser matrix grains. The latter are anisotropic in reflected light and are either still preserved as marcasite or are marcasite relicts. (e) Details of the different textured replacement of the septum margin (between *white arrows* in (c)). The lamellar texture probably is a relict of the earlier lamellar structure of the septal aragonite.

levels of iron sulfide decline with increasing pH. When carbonates dissolve, pH increases and thus forces precipitation of iron sulfide. Chemical modeling suggests, however, that this process is unlikely during early diagenesis (Canfield and Raiswell, 1991). Nonetheless, even the shells of still living mollusks can be pyritized (Srivastava, 1975; Clark and Lutz, 1980), a process favored by pore waters with high levels of dissolved iron and excretion of microbially metabolizable organic substances by the mollusks (Reaves, 1984). In essence, the mollusks supported a sulfidic microenvironment and attracted iron from surrounding (anoxic-nonsulfidic) pore waters. This same basic scenario probably also applies to decomposing organic matter within dead mollusks, leading to shells encrusted or infilled with pyrite (Hudson, 1982). Hudson (1982) distinguished chamber linings (Figure 9), stalactitic pyrite, and over-pyrite (on outer shell surface), all of them mostly consisting of well-crystallized equant pyrite. For the potential impact of intermittent reoxidation of sedimentary iron sulfides on pH levels, carbonate precipitation, and rapid precipitation of the pyrite dimorph marcasite to promote shell encrustation, see the discussion on marcasite formation below.

Soft tissue preservation

The preservation of soft tissue by pyritization is another marvel of fossilization, with well known examples from

the Hunsrück Slate (Stürmer, 1985), Beecher's trilobite bed (Cisne, 1973; Briggs et al., 1991), and the Burgess Shale (Conway Morris, 1986). Ongoing research has been producing a stream of exceptional soft bodied fossils that are preserved in pyrite, such as worms (Gabbott et al., 2004; Farrell and Briggs, 2007), crinoids (Kammer and Ausich, 2007), and plant tissues (Grimes et al., 2001). Pyritization can occur by infilling of cellular cavities, by preferential replacement of more readily decomposed components, and by pyrite coatings on easily degraded soft parts (Canfield and Raiswell, 1991). The latter process may be aided by microbial coatings (Wuttke, 1983) on the decomposing tissues that help to stabilize chemical gradients around the decomposing material. Framboidal, clustered, and aggregated pyrites are the most commonly observed type in this style of preservation. Even microbial cells and textures can be preserved under the right circumstances (Figure 10). With regard to preservation fidelity, soft tissue preservation by pyrite does not preserve as much detail as preservation in a phosphate matrix.

Degree of pyritization (DOP)

A widely used proxy for paleo-oxygenation, DOP is defined (Raiswell et al., 1988; Raiswell and Canfield, 1998) as

$$\text{DOP} = \text{pyrite Fe} / (\text{pyrite Fe} + \text{"reactive iron"})$$

Iron Sulfide Formation, Figure 10 SEM images of microbial remains preserved in early diagenetic coated iron sulfide grains (ooids and oncoids) from the Ordovician Winnipeg Formation, Saskatchewan, Canada (from Schieber and Riciputi, 2005). (a) Filamentous structure (*white arrows*) in slightly etched iron sulfide cortex. Note multiple filaments in the upper part of the picture. In the uppermost part of the picture the filaments merge into a sheet-like structure, potentially remnant of a biofilm. (b) Typical recrystallized appearance of an outermost cortex surface (unetched). Most crystals are pyrite octahedra. Between these crystal pavements one finds remnant patches of an earlier surface ((c), unetched). The latter has a lumpy appearance and consists of tightly packed clusters (a few microns in size) of iron sulfide grains. Close-ups of these clusters ((d), unetched) show that they actually consist of an ovoid smooth walled structure (*black arrow*) that is overgrown by iron sulfide grains. These are interpreted as microbes that were preserved in an iron sulfide matrix. Image (e) (unetched) shows that the smooth surfaces of these ovoids are typically perforated by irregularly shaped openings ((e), *black arrows*), comparable to wall structures seen in experimentally pyritized microbes (Bubela and Cloud, 1983).

An extraction with dithionite or 1 N HCl is supposed to mimic reactive iron dissolution in reducing sediments (Canfield, 1989; Leventhal and Taylor, 1990). The highly reactive iron fraction in sediments is defined as the sum of dithionite or 1 N HCl leachable iron, and iron in acid volatile sulfides (AVS). What DOP presumably measures is the completeness of the conversion of reactive iron into pyrite via microbial sulfate reduction during early diagenesis. The underlying premise is that DOP increases as the degree of environmental oxygenation decreases. Because of the need for sufficient quantities of organic matter and reactive iron, measurements of DOP typically focus on carbonaceous mudstones. DOP values below 0.45 are considered indicative of aerobic bottom waters, and those above 0.45 are thought to mark restricted bottom water conditions. Values above 0.75 are considered to indicate anoxic or even euxinic bottom waters (Raiswell et al., 1988). However, the DOP method should not be applied uncritically, because limitations of either metabolizable organic matter or of reactive iron can lead to DOP values that are not reflective of the actual environment (as calibrated by Raiswell et al., 1988). Several other constraints on DOP application, such as outcrop weathering, maturation, and age of rock are summarized by Raiswell et al. (1988).

DOP as an environmental indicator can also be invalidated as a consequence of sedimentary processes. Any reworking and winnowing of pyrite bearing sediments will increase the pyrite content of the sediment, without simultaneously raising the reactive iron content, and as a result the DOP can rise simply as a result of wave or current reworking. In mudstones, indications of reworking at the mm to cm scale will often go undetected (Figure 11), and can lead to inflated DOP values that are incompatible with the levels of oxygen restriction suggested by observations of frequent reworking and bioturbation (Schieber, 2001, 2003).

Marcasite and its implications

Background on marcasite

Reports of marcasite in terrigenous clastics are mainly associated with coal deposits (e.g., Nayar, 1946; Read and Cook, 1969; Wiese et al., 1987). Marcasite occurs either in the coal seams themselves, or in the roof shales, prompting Krumbein and Garrels (1952) to propose an acidic bog/peat association as the characteristic environment for marcasite formation. There have, however, been a sufficient number of diagenetic marcasite occurrences reported from normal marine sediments (e.g., Maynard and Lauffenburger, 1978; Rykart, 1983; Jowett et al., 1991; Schieber, 2002b, 2007), as well examples of marcasite that has inverted to pyrite (e.g., Bannister, 1932; Van Horn and Van Horn, 1933), to suggest that it might be more widespread in the marine realm than commonly appreciated. If this is in fact the case, and if acidic conditions are indeed a basic requirement for marcasite formation, we have an obvious problem to reconcile these

Iron Sulfide Formation, Figure 11 Reworked pyrite in shale successions. Image (a) is a photograph of a polished specimen, and all others are SEM photomicrographs (backscatter images). (a) Ripple cross-laminated lag deposit that consists mainly of spherical polyframboid fills of algal cysts (Schieber and Baird, 2001). Devonian Genesee Formation, New York, USA. (b) A horizon with abundant reworked flattened polyframboid clusters (comparable to those in Figure 6b). Devonian Chattanooga Shale, Tennessee, USA. (c) Lamina with abundant reworked pyrite framboids. Devonian Chattanooga Shale, Tennessee, USA. (d) Details of framboid-enriched lamina from (c). Shows how reworked pyrite framboids are filling spaces between larger silt grains and have been deformed due to compaction. Devonian Chattanooga Shale, Tennessee, USA.

basic realities with our current understanding of early diagenesis of marine sediments.

As pointed out above, the paragenetic relationships between sedimentary iron sulfide minerals are still poorly understood (Rickard and Morse, 2005). An essential guidepost for thinking about marcasite in sedimentary environments have been experiments conducted by Murowchick and Barnes (1986) that showed that marcasite is the dominant iron disulfide below pH 5. These experiments are consistent with results from much earlier work by Allen et al. (1914) and are also consistent with subsequent work by Schoonen and Barnes (1991a, b) and Benning et al. (2000). Thus, the relative abundance of pyrite versus marcasite in sediments should be a function of pH. Because marine waters have a slightly alkaline pH of approximately 8, it has been presumed that marcasite cannot form in marine sediments during early diagenesis (e.g., Rickard et al., 1995). Yet, regardless of this, early diagenetic marcasite unquestionably occurs in marine sedimentary rocks (Maynard and Lauffenburger, 1978; Siesser, 1978; Rykart, 1983; Jowett et al., 1991; Schieber, 2002b; Schieber and Riciputi, 2005; Williams et al., 2003).

Detecting marcasite

Characteristic morphologies, such as “spearhead” twins and “cockscorn” crystals can be used to identify marcasite. However, morphology does not tell us whether the

marcasite has inverted to pyrite and the approach does not work for dense masses of crystals. As long as crystallites are large enough, it is comparatively easy to differentiate marcasite from pyrite with a petrographic microscope in reflected light mode (Ramdohr, 1975), and it is also possible to detect marcasite that has inverted to pyrite (Murowchick, 1992). For micron scale grains a new technique, “electron backscatter diffraction” (EBSD), can be applied for identification with an electron microscope. EBSD allows phase identification of submicron mineral grains and is widely used in material sciences (Prior et al., 1999; Schwartz et al., 2000).

Marcasite in sedimentary rocks

Marcasite is probably much more widespread in marine clastics than commonly assumed. It occurs as a cement mineral in marine lag deposits associated with sequence boundaries, in condensed intervals, and even in shales. Lag deposits with marcasite occur, for example, in Late Devonian shale successions of the eastern USA (Schieber, 2007). The Late Devonian Chattanooga and New Albany Shale successions contain laterally continuous erosion surfaces that compartmentalize this black shale succession into a stack of depositional sequences (Schieber, 1998a, b; Schieber and Lazar, 2004). These erosion surfaces imply substantial erosion and winnowing of previously deposited black shale during low stands of sea level (Schieber and Riciputi, 2004). The associated lag deposits contain

fish bone debris, conodonts, *Lingula* shells, quartz grains, and abundant pyrite in the form of reworked concretions and form conspicuous rust stained horizons in outcrop (Figure 12a).

In polished thin section pore filling iron sulfides show typical marcasite morphology (Figure 12b). Overall, these lags may contain 30–40% iron sulfides by volume. Loose packing of framework grains indicates precompaction cementation with marcasite. Detrital pyrite grains in these lags are often variably rounded due to mechanical reworking and show etch and corrosion pits on the surface of detrital pyrite grains that are in turn infilled and overgrown by marcasite (Schieber, 2007).

Terrigenous clastic sediments contain at best a few percent reactive iron in the form of iron oxyhydroxide coatings on terrigenous grains (Carroll, 1958; Berner, 1969). Thus, the high iron concentrations in lag deposits with up to 40% iron sulfide require a mechanism for iron enrichment, and in the Phanerozoic at least the iron was most likely reworked from underlying strata (see above). In essence, sedimentary pyrite grains need to be eroded and winnowed in order to add more iron to the surficial layer, a process favored by stratigraphic condensation when net sedimentation rates are negative (Schieber and Riciputi, 2005; Schieber, 2007).

After mechanical enrichment, however, a portion of the sulfide iron has to be remobilized to form the observed overgrowths and pore-fill cements. Preexisting grains are destroyed, either wholly or partially, in order to supply dissolved (Fe^{2+}) or readily soluble iron (e.g., $\text{Fe}(\text{OH})_3$) for the growth of new iron sulfides. Corrosion features on reworked iron sulfide grains (Schieber and Riciputi, 2005; Schieber, 2007) are evidence for iron sulfide destruction according to the following reaction:

This reaction produces acidity and dissolved ferrous iron. Further oxidation of iron (see following equation) produces iron hydroxide and further acidity.

The newly formed iron hydroxides are likely to coat surface sediment grains and would remain in the surficial sediment layer. The associated lowering of pore water pH also promotes large pore water concentrations of Fe^{2+} (Maynard, 1983). Such a setting favors reprecipitation of marcasite in the presence of H_2S influx from underlying sediments (Murowchick and Barnes, 1986; Schoonen and Barnes, 1991a, b; Benning et al., 2000).

For sandy lags the presence of marcasite and partial dissolution of reworked pyrite grains are probably a good indicator that a “reoxidation” model for marcasite formation is applicable (Schieber and Riciputi, 2005; Schieber, 2007). In shales with abundant pyrite a comparable sequence of events may be caused by downward oxidation of previously deposited muds. Potential examples are stratiform horizons of iron sulfide concretions in black shale successions (Figure 13). Where these nodule horizons occur, a gray shale bed is typically found just above them (Figure 13a), and the concretions have a flattened radial fibrous habit, a morphology suggestive of marcasite (Figure 13b).

Reoxidation of reducing organic and iron sulfide-rich sediments, also termed “burndown,” has been studied extensively in the context of Quaternary Mediterranean sapropels (e.g., Jung et al., 1997), and marcasite in shales can potentially be used as a mineral-based indicator of burndown events.

Although the generally finer grain size of diagenetic minerals in shales makes recognition of marcasite more difficult, EBSD analysis allows very tiny (micron-size)

Iron Sulfide Formation, Figure 12 Iron sulfide bearing lag deposits. (a) At left, an exposure of a sequence boundary lag (between arrows) in the late Devonian New Albany Shale. The lag is cemented by iron sulfides. Hammer for scale. (b) At right, a pore space in the lag with acicular “spearhead” twins, typical of marcasite. Electron backscatter diffraction (EBSD) analysis showed that many of the pore-fill iron sulfides still consist largely of marcasite.

Iron Sulfide Formation, Figure 13 Marcasite in late Devonian New Albany Shale, Kentucky, USA. (a) Stratiform horizon of marcasitic nodules (*white arrows*, black vs. gray shales marked by color bar at *right*). The nodules are located about 15 mm below the gray/black shale contact. The large amounts of iron sulfide accumulation at this level suggest that the redox interface stayed in that position for a long time, probably a reflection of zero to very low sedimentation. (b) Close-up of nodules that are broken through and show rims (*white arrows*) of radiating bladed marcasite (*large arrow M*). Note differential compaction.

Iron Sulfide Formation, Figure 14 SEM photomicrographs (backscatter mode) of marcasite in an iron sulfide-enriched lamina in the Cleveland Shale (Upper Devonian, NE Kentucky). (a) Clusters of bladed marcasite grains that form bedding parallel lamina. Note differential compaction around marcasite clusters, suggesting formation when the sediment still had water content in excess of 80%. It also suggests that marcasite in the Cleveland Shale formed within 10–20 cm of the sediment–water interface. (b) Close-up that shows the platy habit of marcasite crystals (marcasite identification with EBSD). The reoxidation that is implicit in this observation contradicts earlier interpretations of this shale as euxinic (e.g., Jaminski et al., 1998; Rimmer, 2004).

marcasite grains to be identified in situ. A preliminary application of this technique to shales has detected marcasite in carbonaceous shales that range from Ordovician to Cretaceous in age (Figures 14 and 15).

Unique fossil beds where preservation in pyrite and marcasite has been observed, such as Beecher's trilobite bed (Cisne, 1973) and pyritized ammonoids (Hudson, 1982; Seilacher et al., 1985), are another phenomenon where our "burndown" model could find application. The large stratiform iron buildup that at least some of these deposits represent requires a similar level of stratigraphic condensation as seen in some of the examples above.

Furthermore, iron needs to be mobile to form the observed mineralized and encrusted fossils. Thus, finding marcasite and dissolution features on reworked pyrite grains in pyritic Lagerstätten would support the view that such deposits may have formed during intermittent reoxygenation events.

The pH drop associated with pyrite oxidation during intermittent reoxygenation also explains textural features observed in association with iron sulfide replacement of calcareous shells. Examination of calcareous shell replacement in Carboniferous through Cretaceous mudstones showed marcasite as a common component,

Iron Sulfide Formation, Figure 15 Pyrite polyframboid cluster in Chattanooga Shale (Tennessee, USA) that formed within an algal cyst (dark rim). The infill was examined with EBSD. Marcasite (m) and quartz (Q) grew in the spaces between pyrite framboids (p). The open arrangement of framboids and the differential compaction around the cyst indicate that cementation happened prior to compaction. The marcasite observed here may well have been caused by intermittent pyrite oxidation in surface sediments. The relief in this image is an artifact, a consequence of oblique imaging (70° tilt) in EBSD mode.

Iron Sulfide Formation, Figure 16 SEM photomicrographs (backscatter) of marcasite replacing biogenic calcite. (a) Clam shell in Boquillas Formation (Cenomanian of West Texas). Skeletal marcasite crystals (marked m) grow as radiating clusters and replace calcite (ca). There is also partial replacement of the shell by quartz (marked qu). (b) Brachiopod shells in Barnett Shale (Mississippian of Texas). Shell in center is replaced by marcasite (marked m) that grows as bladed and sharply pointed crystals. Equant pyrite (py) formed toward end of iron sulfide deposition. Calcite shells marked ca, and replacing quartz marked qu.

intimately associated with calcite dissolution and precipitation of diagenetic quartz (Figure 16). This mineralogical triumvirate makes chemical sense because marcasite formation requires low pH, calcite dissolves at low pH, and dissolved silica (from opaline tests) precipitates under low pH conditions.

With regard to carbonate rocks, most published reports of marcasite are from chalks (e.g., Morgan-Jones, 1977; Kelts, 1976). This marcasite is typically in nodule form, measures up to 10 cm across, and shows crystals with marcasite morphology. Nonetheless, XRD analysis frequently shows that this marcasite has inverted to pyrite. There also seems to be an association with phosphate concretions, and thus with reworking, negative net sedimentation, and geochemical “reworking” of iron, just like that observed in marcasite occurrences in sandstones and shales.

Conclusions

The geobiological significance of sedimentary iron sulfides is far reaching. Microbial sulfate reduction as a metabolic pathway is of great antiquity and dates back to at least the early Archean (3.47-Ga; Shen and Buick, 2004). From that time onward, global cycling of sulfur and carbon has been essential for controlling the amount of oxygen in the Earth’s atmosphere (Berner, 2001), and some have even speculated that the emergence of life itself is tied to sulfur chemistry on the early Earth (e.g., Russell and Hall, 1997). It also appears that in itself oxygen buildup during the Precambrian led to the evolution of increasingly complex biochemical networks among microbes and eventually even to the evolution of complex life forms (Raymond and Segrè, 2006). The iron sulfides that we find in the rock record are a substantial part of the raw data for understanding the complex interaction of life with the atmosphere and the oceans. Every bit of that record, be it in the form of isotope shifts (e.g., Goldhaber, 2003), proportions and distribution of different iron sulfides, sulfide textures, stratal distribution, enclosed and preserved micro- and macro-fossils, as well as subsequent alterations of these minerals, is valuable for understanding chemical changes that affected the biosphere on the local, global, and temporal scales.

For the rock record, the enduring product of all these processes is the iron sulfide pyrite (FeS_2). Yet, the dimorph of pyrite, marcasite, can still be recognized in sedimentary rocks as old as Proterozoic (personal observations) and probably played a much larger role than commonly appreciated. In the minds of many geologists, the presence of iron sulfides in sedimentary rocks is associated with anoxic environmental conditions. In reality, however, once iron sulfides begin to form localized concentrations, be it in the form of micron-size framboids or fist-size concretions, one can imply that oxygen must have been close by. As elaborated repeatedly above, in order to form even microscopic features like pyrite framboids, iron should be able to migrate through the pore waters, and

those conditions only occur near the redox interface that “separates” deeper sulfidic from shallower oxygenated pore waters. Fundamentally, this holds true even in the most classical anoxic-euxinic locale of all, the Black Sea. There, pyrite framboids do not form in the sulfidic bottom waters, but form again at the redox interface where these waters come in contact with oxygenated surface waters (Wilkin et al., 1996). The bulk of sedimentary iron sulfides in the rock records marks the interface between the anoxic and oxic worlds; they should not be taken as an indicator of environmentally pervasive anoxia.

ISOTOPE FRACTIONATION (METAL)

Ariel D. Anbar¹, Silke Severmann²

¹Arizona State University, Tempe, AZ, USA

²Rutgers University, New Brunswick, NJ, USA

Definition

Variations in the abundances of the isotopes of metals, especially transition metals, arising from physical or chemical processes that discriminate among the isotopes of a given element.

Overview

Research into isotope fractionation of transition metals, alkaline earth metals, and metalloids is advancing rapidly

as a result of analytical developments. As of this writing, fractionations have been reported for more than a dozen such elements (Figure 1). These investigations are heavily motivated by geobiological considerations. In particular, there is wide interest in the use of these new isotope systems as biosignatures and as proxies for the

Isotope Fractionation (Metal), Figure 1 Observed range of isotopic variations in modern and ancient natural samples for a selection of metals and metalloids. All values are expressed in delta notation [parts per 1,000 (‰) per atomic mass unit], normalized to average Bulk Silicate Earth (indicated by the gray vertical line). Blue diamonds indicate the average isotope composition of modern seawater, where data are available. IRON SULFIDE FORMATION

Jürgen Schieber
Indiana University, Bloomington, IN, USA

Definition

There has been a great deal of research into the formation of sedimentary iron sulfide minerals because their history is intertwined with the biogeochemical cycles of iron, sulfur, carbon, and oxygen (Berner, 2001). Iron sulfides occur in sediments from a wide range of depositional environments, from the deep sea to the nonmarine, and the principal mineral in the rock record is pyrite (FeS₂, cubic). Its dimorph marcasite (orthorhombic) is considered metastable and apt to invert to pyrite over geologic time (Murowchick, 1992), but is probably more widespread than commonly acknowledged (Schieber, 2007). Presumed precursor minerals of sedimentary pyrite are mackinawite (FeS_{1-x}) and greigite (Fe₃S₄), minerals that impart a black coloration to modern reducing sediments (Goldhaber and Kaplan, 1974). Both are metastable and transform over time into pyrite or a mixture of pyrite and pyrrhotite (Berner, 1967). Pyrrhotite, hexagonal FeS, is thermodynamically stable in sediments (Berner, 1967), but extremely rare in modern or ancient sediments (Kobayashi and Nomura, 1972) due to kinetic limitations (Canfield and Raiswell, 1991).

Mackinawite and greigite are also known as acid-volatile iron sulfides (AVS) because in contrast to pyrite and marcasite they are readily soluble in HCl. Mineralogically, greigite is the sulfur analog of magnetite and is indeed strongly ferromagnetic (Dekkers and Schoonen, 1996). It can be formed by magnetotactic bacteria and dominates the magnetic properties of some modern sediments and

ISOTOPES AND GEOBIOLOGY

Jochen Hoefs
University of Göttingen, Göttingen, Germany

Definition

It has long been recognized (e.g., Thode et al. (1949), Craig (1953) and Wellman et al. (1968)) that biological processes significantly fractionate the isotopes of C, N, and S, leading to characteristic *biosignatures* in sedimentary rocks that will be more or less preserved in the geological record. In the following, a brief overview is given of the major isotope fractionation processes in the biosphere and the geosphere. Special attention will be paid to secondary bacterial activity after deposition of the organic matter. Questions of general interest are isotopic indicators of early life on Earth and on Mars. A note of caution, however, is given whether abiogenic processes may lead to isotope compositions similar to that of biological activity.

Carbon isotope fractionation during photosynthesis

Early reviews by O’Leary (1981) and Farquhar et al. (1989) have provided the biochemical background of carbon isotope fractionations during photosynthesis, with more recent accounts by Hayes (2001) and Freeman (2001). The main isotope-discriminating steps during biological carbon fixation are (1) the uptake and intracellular diffusion of CO_2 and (2) the biosynthesis of cellular components. Such a two-step model was first proposed by Park and Epstein (1960):

From this simplified scheme, it follows that the diffusional process is reversible, whereas the enzymatic carbon fixation is irreversible. The two-step model of carbon fixation clearly suggests that isotope fractionation is dependent on the partial pressure of CO_2 , i.e., $p\text{CO}_2$ of the system. With an unlimited amount of CO_2 available to a plant, the enzymatic fractionation will determine the isotopic difference between the inorganic carbon source and the final bioproduct. Under these conditions, ^{13}C fractionations may vary from -17 to -40‰ (O’Leary, 1981). When the concentration of CO_2 is the limiting factor, the diffusion of CO_2 into the plant is the slow step in the reaction and carbon isotope fractionation of the plant decreases.

CO₂ is directly converted by the enzyme ribulose biphosphate carboxylase/oxygenase (“Rubisco”) to a 6-carbon molecule that is then cleaved into two molecules of phosphoglycerate (PGA), each with three carbon atoms (plants using this photosynthetic pathway are, therefore, called C₃ plants). Most PGA is recycled to make ribulose biphosphate, but some are used to make carbohydrates. Free exchange between external and mesophyll CO₂ makes the carbon fixation process less efficient, which causes the observed large ¹³C depletions of C₃ plants.

C₄ plants incorporate CO₂ by the carboxylation of phosphoenolpyruvate (PEP) via the enzyme PEP carboxylase to make the molecule oxaloacetate, which has four carbon atoms (hence C₄). The carboxylation product is transported from the outer layer of mesophyll cells to the inner layer of bundle sheath cells, which are able to concentrate CO₂, so that most of the CO₂ is fixed with relatively little carbon fractionation. Because mesophyll cells are permeable and bundle sheath cells are less permeable, C₃ versus C₄ plants have ¹³C depletions of −18‰ versus −4‰ relative to atmospheric CO₂. Even more complex is C-isotope fractionation in aquatic plants. Factors that control the ¹³C of phytoplankton include temperature, availability of CO₂ (aq), light intensity, nutrient availability, pH, and physiological factors such as cell size and growth rate.

Since the pioneering work of Park and Epstein (1960) and Abelson and Hoering (1961) it is well known that ¹³C is not uniformly distributed among the total organic matter of plant material, but varies between carbohydrates, proteins, and lipids. The latter class of compounds is considerably depleted in ¹³C relative to the other products of biosynthesis. Although the causes of these ¹³C differences are not entirely clear, kinetic isotope effects seem to be more plausible than thermodynamic equilibrium effects.

Organic matter in the geosphere is a complex mixture of source organisms having variable biosynthetic pathways and detrital remains. The determination of ^{δ13}C values of bulk organic matter is thus unable to distinguish among the different carbon sources. Immediately after burial of the biological organic material into sediments, complex diagenetic changes occur in the organic matter. Two processes have been proposed to explain the observed changes in carbon isotope composition: (1) preferential degradation of organic compounds which have different isotope composition compared to the preserved organic compounds. Since easily degradable organic compounds such as amino acids are enriched in ¹³C compared to the more resistant compounds such as lipids, degradation causes a shift to slightly more negative ^δ values. (2) Isotope fractionations due to metabolism of microorganisms produce new compounds having different isotopic compositions than the original source material. A classic example has been presented by Freeman et al. (1990) analyzing hydrocarbons from the Messel

Isotopes and Geobiology, Table 1 ^{δ13}C values of separated individual hydrocarbons (biomarkers) from the Messel shale (Freeman et al., 1990)

Peak	^{δ13} C (‰)	Compound
1	−22.7	Norpristane
2	−30.2	C ₁₉ acyclic isoprenoid
3	−25.4	Pristane
4	−31.8	Phytane
5	−29.1	C ₂₃ acyclic isoprenoid
8	−73.4	C ₃₂ acyclic isoprenoid
9	−24.2	Isoprenoid alkane
10	−49.9	22,29,30-Trisnorhopane
11	−60.4	Isoprenoid alkane
15	−65.3	30-Norhopane
19	−20.9	Lycopane

shale in Germany (see Table 1). While the major portion of the analyzed hydrocarbons reflects the primary biological source material, some hydrocarbons having low concentrations are extremely ¹³C depleted indicating their secondary microbial origin in a methane-rich environment. Later studies, summarized by Peckmann and Thiel (2004), have documented even larger ¹³C depletions (^{δ13}C values as low as −120‰) in various biomarkers that have been formed by diverse methanotrophic taxa.

C-isotope evidence for earliest signs of life on Earth

The idea of using C-isotope compositions of organic matter for the detection of early life dates back to the classic paper of Craig (1953). Already, at that time, it was discussed whether graphitic carbon in old rocks could be identified as being of biogenic origin (Craig, 1954; Rankama, 1954). This controversy about the meaning of graphite ^{δ13}C values from early Archean (3.5–3.8 Ga) rocks has continued till today (e.g., Bolhar et al., 2004). The validity of using carbon isotopes in the search for early life hinges on the assumption that early organic metabolism produced a C-isotope fractionation effect similar to that observed today. In addition, the thermal history of the metasediments has to be considered. In early Archean metasedimentary rocks from Greenland, ^{δ13}C values range from −22 to −50‰, which could be interpreted as biogenic (Mojzsis et al., 1996). Very negative values were measured for tiny particles of reduced carbon within apatite grains, which apparently had been shielded from metamorphic alteration. However, a case also can be made that graphite from Archean rocks may be of abiotic, hydrothermal origin. In recent years, more experimental and natural evidence has been presented that Fischer–Tropsch type reactions may produce abiogenic organic matter with ^{δ13}C values similar to biogenic organic matter (Taran et al., 2007).

Nitrogen

Microorganisms are responsible for all major conversions in the biological nitrogen cycle, which generally is divided into nitrogen fixation, nitrification, and denitrification. Other bacteria return nitrogen to the atmosphere as N_2 . *Fixation* describes the conversion of unreactive atmospheric N_2 into reactive nitrogen such as ammonium, usually involving bacteria. Fixation commonly produces organic materials with $\delta^{15}N$ values slightly less than 0‰ ranging from −3 to +1 (Fogel and Cifuentes, 1993) and is performed in the roots of plants by many bacteria. The large amount of energy needed to break the molecular nitrogen bond makes nitrogen fixation a very inefficient process with little associated N-isotope fractionation.

Nitrification is a multistep oxidation process mediated by several different autotrophic organisms. Nitrate is not the only product of nitrification, different reactions produce various nitrogen oxides as intermediate species. Nitrification can be described as two partial oxidation reactions, each of which proceeds separately. Oxidation by *Nitrosomonas* ($NH_4 \rightarrow NO_2$) followed by oxidation by *Nitrobacter* ($NO_2 \rightarrow NO_3$). Because the oxidation of nitrite to nitrate is generally rapid, most of the N-isotope fractionation is caused by the slow oxidation of ammonium by *Nitrosomonas*. In N-limited systems, fractionation is minimal.

Denitrification (reduction of more oxidized forms to more reduced forms of nitrogen) is a multistep process with various nitrogen oxides as intermediate compounds resulting from biologically mediated reduction of nitrate. Denitrification takes place in poorly aerated soil and in stratified anaerobic water bodies. Denitrification causes the $\delta^{15}N$ values of the residual nitrate to increase exponentially as nitrate concentrations decrease. Experimental investigations have demonstrated that fractionation factors may change from 10‰ to 30‰, with the largest values obtained under lowest reduction rates. Table 2, which gives a summary of observed N-isotope fractionations, clearly indicates the dependence of fractionation factors on nitrogen concentrations and demonstrates that

Isotopes and Geobiology, Table 2 Naturally observed isotope fractionation for nitrogen assimilation (after Fogel and Cifuentes, 1993)

N_2 fixation	−3 to +1‰
NH_4^+ assimilation	
Cultures	
Millimolar concentrations	0 to −15‰
Micromolar concentrations	−3 to −27‰
Field observations	
Micromolar concentrations	−10‰
NO_3^- assimilation	
Cultures	
Millimolar concentrations	0 to −24‰
Micromolar concentrations	−10‰
Field observations	
Micromolar concentrations	−4 to −5‰

at low nitrogen concentrations, fractionation is nearly zero because virtually all the nitrogen is used.

Sulfur-dissimilatory sulfate reduction

Large ^{34}S -isotope fractionations are induced during bacterial sulfate reduction. Since the early work with living cultures (Harrison and Thode, 1957a, b) it is well known that sulfate-reducing bacteria produce sulfide depleted in ^{34}S by 4–49‰. In general, the rate-limiting step is the breaking of the first S–O bond, namely the reduction of sulfate to sulfite (Goldhaber and Kaplan, 1974; Brunner et al., 2005).

Despite decades of intense research, the factors that determine the magnitude of sulfur isotope fractionation during bacterial sulfate reduction are still under debate. The magnitude of isotope fractionation depends on the rate of sulfate reduction with the highest fractionation at low rates and the lowest fractionation at high rates. One parameter which remains unclear is sulfate concentration.

Naturally occurring sulfides in sediments and euxinic waters are commonly depleted in ^{34}S by up to 70‰, far beyond the apparent capabilities of sulfate-reducing bacteria in the laboratory. Much of the sulfide produced by sulfate reduction in sediments is reoxidized, often via compounds in which sulfur has intermediate oxidation states that do not accumulate, but are readily transformed and can be further disproportionated by bacteria.

Another factor that is of great importance for the observed sulfur isotope variations of natural sulfides is whether sulfate reduction takes place in an open or a closed system. An “open” system has an infinite reservoir of sulfate in which continuous removal from the

Isotopes and Geobiology, Figure 1 Rayleigh plot for sulfur isotope fractionation during closed-system reduction of sulfate. Assumed fractionation factor 1.025; assumed initial isotope composition of sulfate +10‰.

source produces no detectable loss of material. Typical examples are the Black Sea and local oceanic deeps. In such cases, H_2S is extremely depleted in ^{34}S while consumption and change in ^{34}S remain negligible for the sulfate. In a “closed” system, the preferential loss of the lighter isotope ^{32}S from the reservoir has a feedback on the isotopic composition of the unreacted source material. The changes in the ^{34}S content of residual sulfate and of the H_2S are modeled in Figure 1, which shows that $\delta^{34}\text{S}$ values of the residual sulfate steadily increase with sulfate consumption (a linear relationship on a log-normal plot). The curve for the derivative H_2S is parallel to the sulfate curve at a distance which depends on the magnitude of the fractionation factor. As shown in Figure 1, H_2S may become isotopically heavier than the original sulfate when about two third of the reservoir has been consumed. The $\delta^{34}\text{S}$ curve for “total” sulfide asymptotically approaches the initial value of the original sulfate. It should be noted, however, that apparent “closed-system” behavior of covarying sulfate and sulfide $\delta^{34}\text{S}$ values might be also explained by “open-system” differential diffusion of the different sulfur isotope species (Jørgensen et al., 2004).

Another characteristic feature of microbial sulfate reduction is significant small-scale spatial variability in S-isotope composition of pyrite. Up to 105‰ variations in $^{34}\text{S}/^{32}\text{S}$ ratios within strongly zoned pyrite was observed by McKibben and Riciputi (1998). This zonation arises from progressive precipitation of sulfide from pore water sulfate enriched in ^{34}S providing more ^{34}S -enriched sulfide.

New insights on sulfur isotope fractionation mechanisms have been obtained from the analysis of the minor isotopes ^{33}S and ^{36}S (Farquhar et al., 2003; Johnston et al., 2005; Ono et al., 2006). By studying all sulfur isotopes with very high precision, these authors could demonstrate that bacterial sulfate reduction follows a mass-dependent relationship that is slightly different from that expected by equilibrium fractionations. As a result, samples with the same $\delta^{34}\text{S}$ value can have different $\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$ values. This opens the possibility to distinguish between different fractionation mechanisms and biosynthetic pathways (Ono et al., 2006). For instance, bacterial sulfate reduction shows slightly different fractionation relationships compared to sulfur disproportionation reactions (Johnston et al., 2005).

When did bacterial sulfate reduction start on Earth?

Considering a typical difference in $\delta^{34}\text{S}$ values of 20–60‰ between marine sulfate and bacteriogenic sulfide in present-day sedimentary environments, similar fractionations in ancient sedimentary rocks may be interpreted as an evidence for the activity of sulfate-reducing bacteria. The presence or absence of such fractionations in sedimentary rocks thus may constrain the time of emergence of sulfate-reducing bacteria. Sedimentary pyrite depleted in ^{34}S has been observed as far back in geological time as the Precambrian. There is, however,

debate about the dating of first onset of bacterial reduction in the geological record.

In early Archean sedimentary rocks, most sulfides and the rare sulfates have $\delta^{34}\text{S}$ values near 0‰ (Monster et al., 1979; Cameron, 1982), which has been interpreted as indicating an absence of bacterial reduction in the Archean. Shen et al. (2001) and Shen and Buick (2004) argued that the large spread in $\delta^{34}\text{S}$ values of microscopic pyrites aligned along growth faces of former gypsum in the 3.47 Ga North Pole barite deposit; Australia represents the oldest evidence for microbial sulfate reduction. By measuring all four stable isotopes ^{32}S , ^{33}S , ^{34}S , and ^{36}S , additional evidence can be gained to decouple hydrothermal versus biological processes (Ono et al., 2006) even when $\delta^{34}\text{S}$ values are inconclusive.

Mars

McKay et al. (1996) have claimed that Martian meteorite ALH 84001 – found in Antarctica – contains evidence of post-Martian life. Various kinds of apparent biosignatures with characteristic isotope compositions have been suggested: organic matter, carbonate minerals, magnetite grains, and sulfide minerals. After intensive investigations during the last years, none of these proposed biosignatures have survived as such.

Carbonates in Martian meteorites have been especially well studied because understanding the formation conditions of the carbonates is crucial in this connection. Despite extensive chemical and mineralogical studies, the environment of carbonate formation has remained unclear. For instance, in situ C-isotope analysis by Niles et al. (2005) gave highly zoned $\delta^{13}\text{C}$ values from +30‰ to +60‰ consistent with a derivation from the Martian atmosphere and suggesting abiotic formation.

Further evidence about a nonbiogenic origin of Martian carbonates (and even less abundant sulfates) has been presented by Farquhar et al. (1989). By measuring $\delta^{17}\text{O}$ and $\delta^{18}\text{O}$ values, these authors observed an ^{17}O anomaly in the carbonates relative to the silicates which they interpreted as being produced by the photochemical decomposition of ozone just as in the Earth’s stratosphere. This finding suggests that carbonates (and sulfates) are derived from atmosphere–regolith interactions on Mars and not from biological activities.

Fe isotopes as biosignatures?

Virtually all reduction from Fe^{3+} to Fe^{2+} at the Earth’s surface is mediated by the metabolism of dissimilatory bacteria. Biological processes, therefore, may produce measurable Fe-isotopic fractionations because the metabolic processing of Fe involves a number of steps such as transport across membranes that may fractionate Fe isotopes. Experiments with dissimilatory Fe-reducing bacteria of the genus *Shewanella* indicate that iron isotope fractionations are a function of Fe(III) reduction rates: at low rates the produced Fe^{2+} is isotopically depleted by 1.3‰, whereas the depletion is up to 3‰ at high rates (Johnson et al., 2005).

Iron isotope fractionation has also been observed during bacterial Fe oxidation (Croal et al., 2004). Fe(II) oxidizing phototrophs may produce under anaerobic conditions a ferrihydrite precipitate that is 1.5‰ higher than the aqueous Fe(II) source. Controversy still exists whether the iron isotope variations observed in microbial experiments are primarily controlled by kinetic or nonbiological equilibrium factors. Since abiotic iron reduction/oxidation reactions may reveal fractionations similar in direction and magnitude to microbial reactions (Johnson et al., 2002; Skulan et al., 2002), the presence of Fe isotope variations is not in itself conclusive evidence of biotic activity. This complicates the ability to use iron isotopes to identify microbiological processing in the rock record (Balci et al., 2006).

Conclusions

“Biological processes fractionate the stable isotopes of C, N, S, and Fe in a characteristic way leading to biosignatures in the geosphere. Such isotope fingerprints have been used as indicators of early life on Earth and Mars. Since abiological processes sometimes may lead to isotope compositions comparable to biological processes, isotope biosignatures have to be applied with care.”

ISOTOPES, RADIOGENIC

Bent T. Hansen
 University of Göttingen, Göttingen, Germany

Definition

Radiogenic nuclides (more commonly referred to as “radiogenic isotopes”) are produced by a process of radioactive decay. Radioactive decay means that unstable isotopes (mother nuclides) are spontaneously transferred

into stable isotopes (daughter nuclides) by emission of particles and loss of energy (radioactive radiation).

Introduction

The radioactive decay provides an accurate method of measuring the ages of rocks and minerals. This possibility was recognized both by Rutherford (1906) and Boltwood (1907) at the beginning of the twentieth century. However, the measurement and interpretation of variations in the isotopic composition of certain elements in natural materials were not possible until modern mass spectrometers were developed based on the design by Nier (1940). After the World War II, isotope determinations became an important tool in modern geology, geochemistry, and geobiology not only for dating geological processes, but also for investigations of climate change, environmental, and biological parameters. The most frequently used systems are Rb/Sr, Sr/Sr, Sm/Nd, Nd/Nd, U/Pb, and Pb/Pb. In the following, typical examples of the most common radiogenic isotope applications are presented.

Strontium isotopes

There are four stable isotopes of Sr: ^{88}Sr , ^{87}Sr , ^{86}Sr , and ^{84}Sr . All but ^{87}Sr are nonradiogenic (that is, not the products of radioactive decay), whereas ^{87}Sr is produced by radioactive decay of ^{87}Rb (half-life 0.488×10^9 years). The $^{87}\text{Rb} \rightarrow ^{87}\text{Sr}$ radioactive decay pair has therefore produced different $^{87}\text{Sr}/^{86}\text{Sr}$ ratios depending on the age and the amount of Rubidium in the material investigated. For more than half of the century, the Rb/Sr system is one of the most frequently used decay systems for dating geological events.

The isotopic composition of strontium is not only used for dating purposes, but also has turned out to be a universal tool for describing a variety of geological, biological, and environmental processes.

Groundwater and basement brines

Strontium is easily dissolved in water. The advantage of the strontium isotopic system is that the isotopic composition assumed till recently will not be changed by fractionation processes; it means that strontium in circulation depends on the $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of the rocks and minerals that interact with water at or near the surface of the Earth. The Sr isotope composition of groundwater aquifers is constant over years, independent of the amount of rainfall, as demonstrated in a recent study by Klaus et al. (2007). Investigations in the Bangkok Metropolitan Area showed that the $^{87}\text{Sr}/^{86}\text{Sr}$ ratios are useful tools to characterize groundwater flow and related biological and environmental processes.

Strontium isotope variations also play an important role in evaluating the suitability of crystalline rocks for geological disposal of nuclear waste. At the Hard Rock Laboratory at Äspö in southern Sweden, Sr isotope composition of groundwater has been investigated by Peterman and Walin (1999) down to a depth of 850 m from boreholes. Microbial

ICHOLOGY

Murray K. Gingras, Kurt O. Konhauser
University of Alberta, Edmonton, Alberta, Canada

Definition

Ichnology is the study of fossilized, generally macroscopic, animal–sediment interactions. This includes morphological, textural, and local compositional effects related to the animal’s activities. Similar studies in modern sediments are referred to as neoichnology.

Overview

Ichnological studies comprise a wide range of animal–sediment interactions. The scope of animal–sediment interactions was broadly established by Seilacher (1967). He showed that various animal activities, including motility, dwelling, grazing, farming, scavenging, predation, and sessile feeding, are represented by ichnofossils (also referred to as trace fossils).

Bioturbation is the displacement of sediment by animals. In marine environments, common mediators of bioturbation include worm-form animals (such as nemerteans, polychaetes, and hemichordates), marine crustaceans, bivalves, motile echinoderms, sponges, and sea anemones.

Ichnofossils can form from impressions on the sediment surface, intrusion into the sediment, or from excavation of sediment. The former can be thought of as tracks and trails, whereas intrusions and excavations are generally represented by burrows, shafts, and tunnels. Biodeformation structures may result from intrusive activities in loose or fluid-rich sediment. Intrusive, excavatory, and biodeformational structures impact the sedimentary and geochemical character of the surrounding sediment. Traces also incorporate, rework, and redistribute organics

in sediment. This influences the geochemical zonations associated with sedimentary surfaces, and in this regard, bioturbation can be viewed as a diagenetic process.

Biomechanical alteration of sediment texture

Burrowing organisms significantly alter the physical character of a substrate. The changes involved include redistribution of grain sizes (vertically and laterally), modification of grain size, sediment compaction, and sorting (summarized in Bromley, 1996). The physical manifestations of bioturbation are variable depending on the intrusive process employed by the animal (i.e., inversion, compression, excavation, or backfill).

In clastic sediments, the most important result of bioturbation is the rearrangement of coarse *versus* fine grains. This results in an alteration of permeable pathways in the sedimentary media that can influence diagenetic reactions. In carbonate sediment, grain-size reduction probably represents the most significant substrate modification (Chow and Longstaffe, 1995). Reduction of substrate grain size permits a larger surface area to interact with diagenetic fluids and provides more nucleation sites in a given volume.

Biochemical alteration of sediment texture

An important result of bioturbation is the incorporation of localized, concentrated organic material in the form of mucus or feces. Burrow-associated organics induce a geochemical microenvironment that may extend several centimeters, or even decimeters, into the substrate. In well-aerated sediments, burrow linings comprising agglutinated, fecal or primary organic material contain the most concentrated local sources of organic material. These burrows therefore provide excellent substrates for bacterial colonization. Grazing and mining of intact organic remains further lead to their disintegration and introduce larger surface areas for microbial respiration. Moreover,

the ingestion of refractory organic carbon can lead to the excretion of more labile fecal pellets (Lee, 1992).

With most intrusive bioturbation, the sediment–water interface increases in surface area as a result of infaunal animal colonization. The larger (and deepened) sediment–water interface alters chemical fluxes between the sediment and water column. Animals that pump water through their burrow (bioirrigation) increase the rate of chemical flux. Most notably, irrigation of worm burrows with oxygenated seawater results in increased downward and lateral diffusion of O₂, which then affects the oxidation of redox-sensitive elements. For the aforementioned reasons, the accepted scheme of biogeochemical zones in sediment is an oversimplification. Bioturbation influences the solid phase and pore-water properties of sediment by increasing the transport of diagenetic reactants and products across the sediment–water interface. Consequently, surficial sediments cannot be considered a homogeneous medium characterized by one-dimensional vertical diffusion. They are, instead, heterogeneous and intensively mixed with a complex spatial distribution of biogeochemical zones that are difficult to accurately resolve (Aller, 1980).

Metal ion enrichment in ichnofossils

Cation enrichment in burrow linings is the result of sorptive processes. Metals concentrate in burrow linings in three ways: (1) adsorption, as oxide or oxyhydroxide coatings on to the high-energy surfaces provided by fine-grained particles (silt and clay); (2) as sulfide or phosphate phases under reducing conditions; or (3) associated with organic material (as adsorbed coatings or forming organo-metallic complexes) (Over, 1990). The relative importance of each type of enrichment mechanism varies with the depth of burrow penetration, the grain size/composition of the sediment, and bottom-water and pore-water composition.

Ichnofossils and cementation

Trace fossils commonly influence local cementation patterns by changing the sediment texture, its redistribution, and local composition (Gingras et al., 2004). They also facilitate the accumulation of microbial communities, and through their chemoheterotrophic metabolisms, the microbes can alter pore-water chemistry and saturation states. Ichnofossils also possess higher metal concentrations which can serve as nucleation sites for authigenic mineral formation. Although ichnofossils have been strongly linked to the distribution of microorganisms, there is no existing model associating trace fossil diagenesis to microorganic process.

Summary

The presence of ichnofossils/bioturbation in a sedimentary substrate has the effect of altering sediment distribution and permeability pathways. Moreover, the redistribution and stowage of organics in and around

ichnofossils strongly influence the distribution of microorganisms associated with the sedimentary surface. This has an impact on the nature and distribution of biochemical zonations in sediment. The mechanical and (bio)chemical nature of trace fossils influences diagenetic processes.

Definition

Immunolocalization: Technique using specific antibodies to localize macromolecules (proteins, polysaccharides) within biological material (subcellular fractions, cells, tissues, biofilms).

Introduction

Immunolocalization is based on the detection of specific targets (“antigens”; mostly proteins or polysaccharides) in biological samples (cells, tissue, biofilms) by antibodies

as probes. Regularly, antibodies of IgG subtype (Figure 1a) and IgM and IgA subtypes are used. The antibodies may be monoclonal (i.e., identical molecules that recognize only one epitope, which is a short stretch of amino acids or sugar molecules) or polyclonal (a set of antibodies directed against a mostly undefined variety of epitopes on the surface of a larger molecule or a cellular component). Specific non-covalent binding is brought about by the hypervariable region of the antibody (paratope), exactly fitting to an epitope. The hypervariable regions are the tip parts of the Y-shaped arm of the antibody (Figure 1a). All other parts, including the Fc-part, are structurally identical within one antibody subclass. Localization of the antigen is only possible when the specific (or primary) antibody ("probe") binds to a marker. A variety of antibody-marker systems are available for different applications (Figure 1b; see below). The marker may be coupled by different methods to the probe (Hoppert, 2003):

- By direct coupling of the marker to the probe prior to use in a localization experiment. The detection procedure requires just one binding step. The method is also termed *direct immunolocalization*.
- By binding of a secondary probe (mostly a secondary antibody) to the Fc-part of a primary antibody after this primary antibody is already bound to the specific target (two-step procedure). The secondary probe is coupled to the marker. The method is also termed *indirect immunolocalization*.
- By binding of tertiary probes to the secondary probe (for signal amplification). Tertiary probes are responsible for binding or deposition of the respective marker.

Immunolocalization in light and electron microscopy

For immunolocalization in (fluorescence) light microscopy, fluorescent dyes are used as markers

(immunofluorescence microscopy). The marker consists of the dye covalently coupled to a protein (e.g., the secondary antibody) that binds to the primary marker, the antigen-specific antibody. It is also possible to detect more than one target in a sample by the use of marker-probe systems with specificities for different targets coupled to fluorescence markers with discernable absorption–emission spectra. Access to the antigen in tissues or embedded samples can be achieved by (cryo-) sectioning or by permeabilization (Goldenthal et al., 1985). For (nonfluorescent) bright field microscopy, marker systems that catalyze enzymatic reactions are used, leading to deposition of dark-stained precipitates at the antigen binding sites (Ramos-Vara, 2005).

For electron microscopy, probes are coupled to colloidal gold as an electron dense marker. As stated for light microscopy, the marker can be directly coupled to the primary antibody, but regularly, a secondary system is combined with a primary antibody. Also, tertiary systems for signal amplifications are used. In equivalence to multiple detections of targets in light microscopy, it is possible to detect more than one target in a sample by use of marker-probe systems with discernable particle sizes of gold colloids. Particle sizes between 5 and 25 nm are used for experiments at the cellular level. Small gold particles may also be enlarged with silver or gold salt solutions for easier localization (Humbel et al., 1995). For epitope mapping in macromolecules, 1-nm markers ("nanogold") are available (Hainfeld and Powell, 2000).

Several modifications of the original immunogold marker technique can increase the resolution and sensitivity of the method. Dodecaborane clusters may be coupled to antibodies or Fab-fragments via polylysine dendrimers. The boronated antibodies have a lower detection limit in immunolocalization experiments than conventional gold conjugates. Detection of boron is performed by element-specific imaging in energy-filtering transmission electron

Immunolocalization, Figure 1 Antibody probes and colloidal gold markers: (a) Schematized structure of an IgG subtype antibody. (b) Primary antibody with bound secondary antibody and colloidal gold marker.

microscopes (Bendayan et al., 1989; Qualmann et al., 1996; Kessels et al., 1996).

Techniques like catalyzed reporter deposition ("CARD") use tertiary markers. CARD is a technique for amplification of a signal, originally designed for Western blotting, but modified for light and electron microscopy. In the first step, a specific primary antibody is coupled to the target. Then, in a second step, a secondary, biotin-tagged antibody is coupled to the primary antibody. A streptavidin–peroxidase conjugate is then bound to the biotin tag. Peroxidase catalyzes the deposition of tyramides indirectly. The tyramide itself is bound to a detectable marker (e.g., again biotin), and may be localized by the use of streptavidin-coupled colloidal gold for detection in the electron microscope (Mayer and Bendayan, 1997). For light microscopy, fluorescent dye-coupled tyramides are used (Wasielewski et al., 1997).

Related techniques

Besides the widely used antibodies, other specific probes for localization of a target may be used. Table 1 gives an overview of the relevant techniques. Lectin proteins have defined specificities to short carbohydrate stretches and are therefore an alternative to antibodies for detection of polysaccharides. They are mainly used for detection of glycosylated residues or polysaccharides on cell surfaces and/or in microbial biofilms (Kämper et al., 2004).

Especially when macromolecules are present in high concentrations, a target based on a substrate-specific enzyme may be applied. Enzyme–substrate interaction may also be detected with a substrate inducing the precipitation of an electron-dense marker to localize an enzyme activity.

Equivalent to in situ hybridization in light microscopy, the electron microscopic approach can allow high-resolution mapping of specific mRNA. The technique

Immunolocalization, Table 1 Techniques for the localization of biological macromolecules by light (LM) and electron microscopy (EM)

Problem	Specimen treatment	Marker system (technique; references)
Localization of specific proteins (antibody-gold/antibody-fluorescent probe) or carbohydrate complexes (lectin-gold/lectin-fluorescent probe) inside cells (LM/EM)	Ultrathin sections of resin-embedded samples subjected to immunolocalization	Antibody-colloidal gold, lectin-colloidal gold (Roth et al., 1980; Horisberger, 1985; Danguy et al., 1988)
Localization of specific proteins on the cell surface or on subcellular particles (EM)	Incubation of cells or subcellular fractions with the marker system prior to resin embedding or direct adsorption on specimen support films	Antibody-colloidal gold, lectin-colloidal gold (Acker, 1988; Rohde et al., 1988)
Localization of single protein epitopes and their relative position to each other on the surface of the object (EM)	Homogeneous protein preparations (especially large proteins or viruses) subjected to localization of epitopes	Antibody, Fab-fragment, (epitope-labeling; Hermann et al., 1991)
Detection of enzyme activities (EM)	Incubation of cells or subcellular fractions with the marker system	Specific enzyme substrate coupled to precipitation of electron dense marker (Hayat, 1973ff; Wohlrab and Gossrau, 1992)
Detection of macromolecular components acting as enzyme substrates (e.g., starch, lipids) (EM)	Labeling of enzyme substrates with gold particles coated with the relevant enzymes in ultrathin sections of samples	Enzyme-colloidal gold (Bendayan, 1985)
Localization of metabolites in the cell (EM)	Incubation of metabolically active cells with the precursor, embedding in conventional resin or by application of cryotechniques, treatment with a specific photoemulsion	Metabolic precursors (e.g., sugars or aminoacids) labeled with radioactive markers (autoradiography; Gregg and Reznik-Schüller, 1984)
Localization of specific DNA or RNA (preferably mRNA) sequences in cells (LM/EM)	Fluorescent in situ hybridization for light microscopy, hybridisation of DNA/RNA of fixed samples with the marker system followed by embedding and sectioning, detection of the marker system by autoradiography or with streptavidin-colloidal gold for electron microscopy	RNA or DNA oligonucleotide labeled with different markers (in situ hybridization; Amann et al., 1995; Egger et al., 1994)
Comparison of immunolocalization targets from overview (low resolution) to subcellular structures (high resolution) (EM)	Ultrathin (and semithin) sections of resin-embedded samples subjected to immunolocalization	Antibody-colloidal gold and antibody-fluorescent probe, lectin-colloidal gold and lectin-fluorescent probe (Takizawa and Robinson, 2003).

may be combined with specific signal enhancement methods (CARD, see above) and is suitable for high-resolution in situ hybridization (Cheung et al., 1999).

For microautoradiography, radiolabeled markers, incorporated into cell structures, are located by exposure to photographic emulsion. The deposition of silver bromide grains on the photoemulsion is detectable by light and electron microscopy. The technique is demanding and difficult to reproduce, though it gives information on processing and distribution of metabolites that cannot be obtained, on a structural level, by other methods (Gregg and Reznik-Schüller, 1984).

Correlative microscopy

The technique of correlative light/electron microscopy allows examination of the same sample at micrometer scale for overview images and at nanometer scale for imaging of features at high resolution. Regularly, (fluorescence) light microscopy and electron microscopy of samples is combined. The marker/probe systems are either suitable for both microscopic techniques at the same time or for combinations of different systems that are detectable either by light or by electron microscopy.

Quantum dots (qdots) are colloidal semiconductor nanocrystals and are detectable in the electron microscope, either as electron dense particles or via element specific imaging. Since qdots exhibit specific absorption/emission spectra in the light, they are also detectable as fluorescent markers. When qdots are coupled to primary antibodies, they are marker-probe systems suitable for both imaging techniques (Nisman et al., 2004).

Though it is possible to visualize ultrathin sections by (fluorescence) light microscopy, sections of several micrometer in thickness (semithin sections) are regularly more suitable. It is possible to obtain nearly identical features of a specimen when one ultrathin and one semithin is

consecutively cut from a specimen. Semithin and ultrathin sections are then processed in different ways, either with marker-probe-systems for immunofluorescence or for immunoelectron microscopy (Figure 2; Takizawa and Robinson, 2003; Wrede et al., 2008).

Correlation of data from immunolocalization may also be performed with other microscopic techniques, such as Raman microscopy, scanning electron microscopy, or atomic force microscopy.

Conclusions

It has already been understood in the first half of the past century that, besides comprehending biochemical or molecular reactions in organisms, the understanding of their organization is of equal importance (Hopkins, 1933). Tools for understanding organization of these processes have been developed consecutively, when methods became available to keep organisms alive or at least well-preserved down to molecular scale. The techniques revealed that the presumption of some early biochemists was right, i.e., metabolic pathways, growth and cell division, even of apparently non-compartmented bacteria, are organized in high ordered, large macromolecular complexes. Future direction of localization techniques will include the application of marker systems for high resolving microscopy systems that will allow observation of living cells down to nanometer scale (Donnert et al., 2006).

IRON SULFIDE FORMATION

Jürgen Schieber
Indiana University, Bloomington, IN, USA

Definition

There has been a great deal of research into the formation of sedimentary iron sulfide minerals because their history is intertwined with the biogeochemical cycles of iron, sulfur, carbon, and oxygen (Berner, 2001). Iron sulfides occur in sediments from a wide range of depositional environments, from the deep sea to the nonmarine, and the principal mineral in the rock record is pyrite (FeS₂, cubic). Its dimorph marcasite (orthorhombic) is considered metastable and apt to invert to pyrite over geologic time (Murowchick, 1992), but is probably more widespread than commonly acknowledged (Schieber, 2007). Presumed precursor minerals of sedimentary pyrite are mackinawite (FeS_{1-x}) and greigite (Fe₃S₄), minerals that impart a black coloration to modern reducing sediments (Goldhaber and Kaplan, 1974). Both are metastable and transform over time into pyrite or a mixture of pyrite and pyrrhotite (Berner, 1967). Pyrrhotite, hexagonal FeS, is thermodynamically stable in sediments (Berner, 1967), but extremely rare in modern or ancient sediments (Kobayashi and Nomura, 1972) due to kinetic limitations (Canfield and Raiswell, 1991).

Mackinawite and greigite are also known as acid-volatile iron sulfides (AVS) because in contrast to pyrite and marcasite they are readily soluble in HCl. Mineralogically, greigite is the sulfur analog of magnetite and is indeed strongly ferromagnetic (Dekkers and Schoonen, 1996). It can be formed by magnetotactic bacteria and dominates the magnetic properties of some modern sediments and

even some ancient sedimentary rocks (e.g., Krs et al., 1990).

Although they also occur in nonmarine sediments, the bulk of sedimentary iron sulfides forms in marine sediments during early diagenesis via microbial reduction of seawater sulfate. The general process of their formation has been elucidated by a number of classical studies (e.g., Kaplan et al., 1963; Berner, 1970, 1984). From a geobiological perspective, iron sulfides are of interest as their presence denotes anoxic and reducing pore waters, because they can preserve minute details of soft tissues (e.g., Briggs et al., 1991; Gabbott et al., 2004; Kammer and Ausich, 2007), because microbial life in pore spaces may be entombed in growing iron sulfide grains (Schieber, 2002a), and because the iron sulfide matrix is apparently able to preserve more complex organic molecules (such as amino acids) for long geologic time periods (Nardi et al., 1994). For an in-depth discussion of sedimentary sulfide formation and the linkage to the global sulfur cycle the reader is referred to an excellent overview by Goldhaber (2003) in the Treatise on Geochemistry.

Pathways to sedimentary iron sulfides

The understanding of iron sulfide formation under Earth surface conditions has largely been informed by extensive laboratory studies (see summary by Morse et al., 1987). Multiple potential pathways for sedimentary iron sulfide (pyrite) formation have been recognized. As summarized by Goldhaber (2003), these include (1) direct precipitation of pyrite from polysulfide bearing solutions, (2) progressive conversion of solid iron monosulfides to pyrite (Figure 1) by polysulfides, (3) reaction of H_2S with a solid iron monosulfide to form pyrite (release of H_2 gas), and (4) reactions that involve iron loss from a solid iron monosulfide precursor through oxidation.

As indicated by this summation, the body of published literature lives by the assumption that iron monosulfides (generic for mackinawite and/or greigite) are necessary precursors for pyrite formation in sediments. Thus, the normal iron sulfide paragenesis in sediments is presumed to proceed from mackinawite over greigite to pyrite (e.g., Wilkin and Barnes, 1996; Benning et al., 2000). The tacit assumption is that sedimentary pyrite cannot form in the absence of acid-volatile iron monosulfides (AVS). Yet, direct evidence for this traditional view is scant. Rickard and Morse (2005) have argued strongly that in numerous studies of modern sedimentary pyrite formation abundant pyrite is produced in the absence of detectable AVS. They argue that many of the equations that describe sedimentary pyrite formation in the literature represent net mass balances and do not describe the actual reaction processes. Rickard and Morse (2005) point out that AVS are not required for reaction pathways that involve polysulfide or H_2S (numbers (2) and (3) from above), and that aqueous FeS clusters could be involved instead of solid monosulfide phases. They propose that the products of the diagenetic sulfide machinery,

Iron Sulfide Formation, Figure 1 SEM photomicrograph of pyrite framboids from modern reducing muds of the Santa Barbara Basin, offshore southern California. The sediment was cored, stabilized in Spurr resin, and polished with diamond paste. At lower right a similar well-formed framboid might be found in ancient mudstones. In the center a less ordered framboid with bright grains that are pyrite (EDS analysis), and gray grains that have about half the sulfur peak intensity (EDS spectra) of typical pyrite grains. The interpretation is that the gray grains are the Fe-monosulfide precursor material (amorphous FeS , mackinawite, ~greigite) that has been the subject of geochemical studies. (Berner, 1970; Sweeney and Kaplan, 1973; Goldhaber and Kaplan, 1974; Murowchick and Barnes, 1987; Wilkin and Barnes, 1997.)

mackinawite, greigite, and pyrite, may form either simultaneously or in no particular order during sediment diagenesis.

The building blocks

Regardless of how sedimentary iron sulfides are ultimately produced, it is instructive to examine where the requisite iron and sulfur come from. Because iron is insoluble in the presence of oxygen, the iron content of sea water and freshwater is extremely low (Stumm and Morgan, 1996). It is, therefore, practical to assume that any iron that is available for iron sulfide formation has to be part of the particulate matter that makes up the sediment. Typical deltaic and marine muds have iron contents that range from 4% to 8% (Calvert, 1976; Chester and Asten, 1976; Aller et al., 1986), but not all of that iron is equally available for diagenetic iron sulfide formation. Although there may be plenty of iron in iron silicates (e.g., biotite, chlorite), release of that iron requires alteration/destruction of the containing silicate, a process that operates more efficiently under the higher temperatures of deep burial diagenesis (Figure 2). Thus, this iron fraction is not available during early diagenesis when the bulk of sedimentary iron sulfides is formed.

Iron Sulfide Formation, Figure 2 SEM photomicrograph of late diagenetic biotite alteration associated with pyrite formation (backscatter (BS) image) in the Devonian Ohio Shale, Kentucky, USA. Pyrite (very bright) forms along cleavage planes near the end of a biotite flake because during alteration these are the places where iron is released. The surrounding pore waters must have contained abundant H_2S . Iron was precipitated as FeS_2 very close to the place where it was released from the biotite lattice, and it was not able to migrate away from its source grain.

The iron fraction that is critical in early diagenesis is in the form of coatings of iron oxyhydroxides on detrital grains (especially on clays; Carroll, 1958), as well as in the form of particulate/colloidal iron oxyhydroxides (e.g., Allard et al., 2004). Of the 4–8% of total iron that we can expect in average muddy sediments, only some 10%, and under very favorable circumstances up to about half, is made available by reducing agents (Gibbs, 1977; Trefrey and Presley, 1982; Canfield, 1989) for the formation of early diagenetic iron sulfides.

Sulfur, of course, is readily available via seawater sulfate in marine sediments, and for surficial sediments the overlying seawater represents an essentially limitless reservoir. Only upon burial, once consumed sulfate can no longer be replenished by downward diffusion, does sulfur become a limiting commodity. In all sediments, the production of H_2S for sulfide formation is accomplished by sulfate reducing prokaryotes that utilize sulfate as an electron acceptor for energy producing chemical reactions. For carbohydrate oxidation this reaction may be written as

Thus, organic matter that can be utilized by sulfate reducing microbes is essential for the operation of the sedimentary sulfide factory. Even in the presence of abundant sulfate, sulfide production will only occur if there is “food” for the microbes. Sulfate reduction equations proposed by Canfield and Raiswell (1991) suggest that it will require about 5 cm^3 of microbially “digestible” organic matter (e.g., lactate, ethanol, acetate, sugar) to precipitate 1 cm^3 of FeS_2 . Thus, low organic matter contents in sediments will tend to limit sulfide production and the amount of iron that can be converted to pyrite.

Above considerations also have implications with regard to where we most likely will find large quantities of iron sulfides in sedimentary rocks. Because pure carbonates typically accumulate far from the influence of terrigenous clastics, the average carbonate rock tends to contain only minor quantities of iron and thus, sedimentary iron sulfides are generally low in abundance. Sandstones, even though they may contain appreciable quantities of iron in the form of iron bearing detrital silicates and as iron oxyhydroxide grain coatings, are comparatively poor in organic matter and thus lack the fuel to drive extensive early diagenetic sulfate reduction. When we do find substantial accumulations of iron sulfides in carbonates or sandstones, they are in the majority of cases due to late diagenetic processes that benefited from higher temperatures and constituent bearing formation waters. Exceptions occur when carbonates or sandstones are interbedded with shales and mudstones, because the latter carry the bulk of iron in the sedimentary mass balance (Taylor and McLennan, 1985). The lion’s share of sedimentary iron sulfides is therefore contained in fine grained terrigenous rocks (shales and mudstones).

Iron sulfide textures

Pyrite, the most commonly reported iron sulfide in sediments, is cubic in structure, and thus cubes and octahedra are common morphologies. In addition to these fundamental forms, iron sulfides are also patterned into a wide range of textural types (e.g., single grains, framboids, pore fill cements, concretions, pyrite cemented layers, and pyritic lags) that carry useful information about conditions during deposition and early diagenesis. From a geobiological perspective, concretionary iron sulfide accumulations are of particular interest because their formation was likely driven by decomposing organic matter. Their morphology varies widely, and many types have been described, such as pyritized burrow tubes, infilling and encrustation of fossils, replacement of fossil hard parts (carbonate shells, bones), and pyritization of soft tissues.

Single grains

As single grains, pyrite may occur as a disseminated component, ranging from less than $1 \mu\text{m}$ to tens of micrometer in size. Yet, while these may indeed be grains that record a single growth episode, etching (e.g., with HNO_3) may reveal internal textures that speak to multistage growth.

Pyrite framboids

Ubiquitous in modern and ancient sediments, pyrite framboids are typically near-spherical in shape, range in diameter from about $1 \mu\text{m}$ to tens of micrometers, and are themselves composed of tiny, discrete, and equigranular pyrite crystallites. They have been the subject of numerous studies, and early on there was an assumption that organic matter (Figure 3) somehow plays a role in their formation (Schneiderhöhn, 1923; Love,

Iron Sulfide Formation, Figure 3 SEM photomicrograph of an etched pyrite framboid in the Devonian Chattanooga Shale of Tennessee, USA. The etching with HNO_3 removed the pyrite crystallites and left behind a honeycomb of organic matter that filled the space between the pyrite grains. The organic matter has the same composition as the unstructured kerogen in the surrounding sample.

1967). Yet, because they can also be produced abiotically in the laboratory (Berner, 1969; Sweeney and Kaplan, 1973), the role of organic matter remains a matter of debate (e.g., Kalliokoski, 1974). The abundantly noted close association of pyrite framboids and organic matter may well be coincidental because the reducing conditions that promote their formation are best developed in sediments with elevated contents of organic matter.

Most pyrite framboids observed in sedimentary rocks consist of microcrysts (Figure 4a; typically cubes, octahedral, or pyritohedra) that show poorly defined to highly ordered packing into spherical aggregates (Wilkin and Barnes, 1997; Ohfuji et al., 2005). The size ratio of microcrysts to framboid diameter is quite variable (Figure 4b). Directly adjacent framboids may show vast differences in diameter/microcryst size ratios (Figure 4b), and also show contrasting microcryst morphology. These textural details probably carry some information about the pore water environment during formation, but at present their significance is poorly understood. Pyrite framboids can survive intact into greenschist grade metamorphism, and can for example, identify slates that originated as marine shales (Figure 4d).

Iron Sulfide Formation, Figure 4 Pyrite framboids in the rock record. All images are SEM photomicrographs (backscatter mode). (a) Moderately well-ordered framboid from the late Devonian New Albany Shale (Indiana, USA). Note differential compaction of clays and organic matter around the framboid, indicating framboid formation prior to compaction when the sediment contained ~80% water. (b) Framboids in modern sediments from the Santa Barbara Basin (offshore southern California, USA). Note the strong differences in diameter/microcryst size ratios and the contrast in microcryst morphology (pyritohedra vs. complex cubes). (c) Framboid consisting mostly of variably size octahedra (Ordovician Powers Steps Formation, Newfoundland). (d) Pyrite framboids that survived low-grade metamorphism and cleavage development ($\pm$ horizontal) in the Ordovician Martinsburg Slate of New Jersey, USA.

The formation processes of pyrite framboids are discussed at length by Wilkin and Barnes (1997), and further perspectives are presented by Ohfuji et al. (2003) and Butler and Rickard (2000). Fundamentally, in order to form framboids within the pore spaces of a sediment, iron should be able to migrate to the site of formation and thus, the pore waters have to be nonsulfidic (anoxic-nonsulfidic; Berner, 1981). Furthermore, in order for iron oxyhydroxides to dissolve in the pore waters, they also need to be free of oxygen. In the idealized sequence of microbial decay reactions in sediments (Brett and Allison, 1998; Curtis et al., 2000), this is known as the “suboxic” zone, and is followed by the “anoxic” zone of sulfate reduction. The boundary between the suboxic and the anoxic zone is also referred to as the redox interface, and it is here where dissolved iron meets sulfide and iron sulfides can precipitate. Pyrite framboids form in that region. Yet, whereas these zones are thought to be layered atop each other in surficial sediments, in reality it is a bit more complex. Every single framboid implies that iron migrated from a surrounding sediment volume to form this localized accumulation, and by default this means that there was a localized source of sulfide that via iron sulfide precipitation maintained the underlying concentration gradient. The sulfide source was probably a colony of sulfate reducing bacteria that prospered around a lump of easily digested organic matter. Thus, rather than simply being a narrow bedding-parallel zone in which dissolved iron interacts with dissolved sulfide, the realm of framboid formation (the redox interface) is heterogeneous. It makes more sense to think of it as “islands” of microbial sulfide production in a “sea” of iron-bearing pore waters (Figure 5), the reducing microenvironments that have been mentioned elsewhere in the literature (e.g., Hudson, 1982).

Whereas in typical sediments the redox interface is situated somewhat below the sediment water interface, there are situations where the redox interface is actually located in the overlying water column, such as in the Black Sea. In euxinic basins, with the lower portion of the water column being anoxic and sulfidic, framboids can grow in the water column near the redox interface and then settle and become part of the accumulating sediments (Wilkin et al., 1996). Wilkin et al. (1997) report that framboids of that origin are rather small (mean framboid diameters $<5\ \mu\text{m}$, narrow size distribution) when compared to those forming in sediments underlying oxic and dysoxic waters (mean framboid diameters $5\text{--}10\ \mu\text{m}$, broad size distribution). The implication of this is that one can use the framboid size distributions of sediments to determine whether they accumulated beneath an anoxic water column. Wignall and Newton (1998) applied this concept to ancient mudrocks and were able to correlate framboid size distributions with paleoecologically based reconstructions of bottom water oxygenation. However, framboid size in sediments may also be influenced by the availability of iron during early diagenesis. For example, a study of framboid size distributions in sediments from the Santa Barbara Basin (offshore southern California) indicates that framboid size distributions primarily reflect conditions within the immediate surface sediment (such as availability of readily soluble iron). Framboid size distributions in annual varves (1984–2004) from the Santa Barbara Basin suggest three euxinic interludes in the past 2 decades, even though seasonal bottom water surveys consistently recorded suboxic to dysoxic bottom water conditions (Schieber and Schimmelmann, 2006). It appears, therefore, that it may not be possible to draw conclusions about water column conditions from pyrite framboid size distributions.

Iron Sulfide Formation, Figure 5 SEM photomicrographs (backscatter mode) of localized pyrite framboid formation in reducing microenvironments of Santa Barbara Basin (offshore southern California) surface sediments. At left, a multichambered calcareous foraminifera with chambers filled by framboids. At right, a framboid filled diatom. Lower right half, imaged in secondary electron (SE) mode (framboids not visible). Upper left half, imaged in backscatter (BSE) mode, the framboids shine through the lower density opaline “lid.”

Polyframmboids

Pyrite frammboids may also occur as larger aggregates, so called polyframmboids. These have been described from sediments of various ages (Schieber and Baird, 2001) and have a tendency to form in cavities of organic remains (Figures 5 and 6). Judging from differential compaction around polyframmboids (Figure 6), they must form prior to any compaction, just like single pyrite frammboids. They also imply iron migration from a surrounding sediment volume that was anoxic but not sulfidic. The difference between polyframmboids and regular pyrite frammboids may simply be a higher iron supply from the pore waters, or alternatively that the “islands” of microbial sulfate reduction are more widely spaced and thus, focus the available iron onto fewer sites of precipitation. Because most marine sediments start out with comparable amounts of reactive iron, the latter scenario is more likely.

Small-scale pyrite aggregates and clusters

Pyrite bodies that consist of coalescing, irregular, rounded clots of small pyrite grains have been described as

aggregated pyrite by Hudson (1982). The cores of individual clots may be small pyrite crystals or pyrite frammboids, and these cores are overgrown by coarser pyrite crystals (Figure 7). In places these overgrown grains show a radiating bladed habit. These overgrown grains tend to form somewhat later in diagenesis, at a point when downward diffusion of seawater sulfate is increasingly restricted (Strauss and Schieber, 1990). This type of pyrite aggregate ranges in size from tens of microns to several millimeters.

Concretions and pyritic layers

Iron sulfide concretions in sediments vary in size from a few millimeters to more than 10 cm. Like other occurrences of sedimentary iron sulfides they are most commonly encountered in mudstones and typically occur in distinct nodule bearing horizons (Figure 13). Although pyrite is usually reported as the sole iron sulfide mineral, careful examination reveals many examples of inverted or extant marcasite within these iron sulfide accumulations (Schieber, 2002b, 2007; Schieber and Riciputi,

Iron Sulfide Formation, Figure 6 SEM photomicrographs of pyrite polyframmboids (backscatter images). Note differential compaction around polyframmboid aggregates. (a) Ordovician Powers Steps Formation, Newfoundland, Canada. Note “squeezing” of frammboids, suggesting initial formation in a confined space (transported?). (b) Devonian Chattanooga Shale, Tennessee, USA. Here, the polyframmboid is still enclosed (black line) in an algal cyst (Tasmanites) that formed the initial reducing microenvironment. The space between frammboids is filled with secondary, coarser pyrite cement.

Iron Sulfide Formation, Figure 7 SEM photomicrographs of pyrite aggregates (backscatter images). (a) Irregularly shaped aggregate consisting of smaller pyrite clots. (b) Small cluster of pyrite clots that still have visible frammboids in their cores. The overgrown pyrite has radiating habit and may have originated as marcasite.

2005). Especially the larger concretions approximate prolate ellipsoids (Figure 8a) and show differential compaction of the surrounding mudstone (Figure 13). These features attest to growth prior to substantial compaction and growth within a stratiform chemical zone (anoxic and nonsulfidic; Berner, 1981). In order for iron to be directed to localized sites of precipitation within this zone, there need to be sites of abundant H_2S production, as, for example, provided by microbial decay of buried organisms (e.g., bivalve, fish). Thus, the interiors of iron sulfide concretions are good targets for finding well-preserved fossils. In order to allow the concretions to grow to large size, this chemical zone has to remain stationary for a long time, probably on the order of thousands of years (Canfield and Raiswell, 1991). Not uncommonly, the iron sulfide concretions in a given layer also add up to a substantial excess of iron relative to the background sediment, suggestive of prior concentration by mechanical and chemical reworking (see Section “Marcasite and its implications”). Thus, horizons with abundant iron sulfide concretions or abundant pore filling iron sulfides imply very slow sedimentation at the time of nodule formation and should also alert us to the possibility of reworking and erosion of underlying sediments (Schieber and Riciputi, 2005). Other options for the formation of iron sulfide-enriched horizons are, for example, to cover iron-oxide rich layers with an organic-rich anoxic sediment drape (Ingri and Ponter, 1986). Migration of a sulfide-rich reduction front into the iron-bearing layer would effectively convert the iron oxides to pyrite.

Hydraulic concentrations (lags)

Because iron sulfide grains are of much higher density than associated silicates and organic matter, they are liable

to be concentrated into lag deposits when the easily eroded surface sediment is reworked by bottom currents and storms. Reworking can be manifest in the form of submillimeter concentrations of pyrite framboids (Figure 11c), as well as in decimeter thick concentrations of a wide variety of sedimentary pyrite grains (Figure 11). Examples are pyrite concretions (Figure 8), pyritized burrow tubes, and pyrite-filled algal cysts (Figure 6b). Lags that contain abundant iron sulfide grains have been described from the rock record in many places (e.g., Baird and Brett, 1991; Schieber, 1998a; Schieber and Baird, 2001). The mechanical enrichment of iron sulfides has two major implications and consequences. First, because of limitations on the initial soluble iron content of sediments, a substantial volume of sediment has to be sacrificed to erosion in order to concentrate all the iron into a single layer. Let us assume, for example, that typical mudstones have about 5% iron. A 5 cm thick lag with about 60% FeS_2 by volume would require that (at a minimum) a 50 cm thick (fully compacted) shale interval be winnowed to provide the necessary iron. Given that early in depositional history the uppermost meters of this shale (mud) had probably still an average porosity of at least 50%, the presence of this lag then implies that at least one meter, and more likely several meters, of sediment was removed.

Iron sulfides and fossil preservation

Replacement and encrustation of calcareous shells

Encrustation and replacement of calcareous shells by iron sulfides are widely observed in the rock record. Typically, an assumption is made that the iron sulfide in question is pyrite, but a case can be made wherein marcasite was involved at least initially (see below). One way to think about calcite/aragonite replacement is that the saturation

Iron Sulfide Formation, Figure 8 A collection of iron sulfide concretions. (a) Oblate concretion from the Devonian Ohio Shale of eastern Kentucky, USA. Probably contains marcasite around the periphery, just like that seen in Figure 13. (b) Discoid-flattened pyrite concretions from the Jurassic Posidonia Shale near Dotternhausen, Germany. These may originally have been marcasitic. (c) Heavily pyrite (plus marcasite?) encrusted ammonite from the Lower Jurassic (Amaltheenton) near Dotternhausen, Germany. The specimen weighs at least 5 kg (courtesy of Dr. M. Jäger, Holcim GmbH). Without pre-concentration of iron in the sediment, it would require all the iron contained in a volume of 250 l of sediment (80% water content, 5% Fe in dry matter) to be concentrated into this concretion. Because iron redistribution is not that efficient, it is more likely that something on the order of 1 m³ of sediment has to be depleted.

Iron Sulfide Formation, Figure 9 Fossil preservation by iron sulfides, SEM photomicrographs. (a) Chamber lining iron sulfides in an ammonite (secondary electron image), Lias delta (Amaltheenton) near Dotternhausen, Germany. The septa of the ammonite (*white arrows*) are now calcitic, and the chamber interior is filled with calcite as well. (b) Close-up of the iron sulfide (bright, backscatter image) encrusted septum. The encrusting sulfides are a mixture of pyrite (framboids) and marcasite (overgrowth). (c) Close-up of encrustation near septum (backscatter image). The marginal areas of the septum (marked between *white arrows*) have a different texture than the areas further away. The latter areas contain pyrite framboids (*black arrow*) in a coarser matrix of blocky to radiating crystals. (d) Close-up of framboids (*white arrows*) in coarser matrix grains. The latter are anisotropic in reflected light and are either still preserved as marcasite or are marcasite relicts. (e) Details of the different textured replacement of the septum margin (between *white arrows* in (c)). The lamellar texture probably is a relict of the earlier lamellar structure of the septal aragonite.

levels of iron sulfide decline with increasing pH. When carbonates dissolve, pH increases and thus forces precipitation of iron sulfide. Chemical modeling suggests, however, that this process is unlikely during early diagenesis (Canfield and Raiswell, 1991). Nonetheless, even the shells of still living mollusks can be pyritized (Srivastava, 1975; Clark and Lutz, 1980), a process favored by pore waters with high levels of dissolved iron and excretion of microbially metabolizable organic substances by the mollusks (Reaves, 1984). In essence, the mollusks supported a sulfidic microenvironment and attracted iron from surrounding (anoxic-nonsulfidic) pore waters. This same basic scenario probably also applies to decomposing organic matter within dead mollusks, leading to shells encrusted or infilled with pyrite (Hudson, 1982). Hudson (1982) distinguished chamber linings (Figure 9), stalactitic pyrite, and over-pyrite (on outer shell surface), all of them mostly consisting of well-crystallized equant pyrite. For the potential impact of intermittent reoxidation of sedimentary iron sulfides on pH levels, carbonate precipitation, and rapid precipitation of the pyrite dimorph marcasite to promote shell encrustation, see the discussion on marcasite formation below.

Soft tissue preservation

The preservation of soft tissue by pyritization is another marvel of fossilization, with well known examples from

the Hunsrück Slate (Stürmer, 1985), Beecher's trilobite bed (Cisne, 1973; Briggs et al., 1991), and the Burgess Shale (Conway Morris, 1986). Ongoing research has been producing a stream of exceptional soft bodied fossils that are preserved in pyrite, such as worms (Gabbott et al., 2004; Farrell and Briggs, 2007), crinoids (Kammer and Ausich, 2007), and plant tissues (Grimes et al., 2001). Pyritization can occur by infilling of cellular cavities, by preferential replacement of more readily decomposed components, and by pyrite coatings on easily degraded soft parts (Canfield and Raiswell, 1991). The latter process may be aided by microbial coatings (Wuttke, 1983) on the decomposing tissues that help to stabilize chemical gradients around the decomposing material. Framboidal, clustered, and aggregated pyrites are the most commonly observed type in this style of preservation. Even microbial cells and textures can be preserved under the right circumstances (Figure 10). With regard to preservation fidelity, soft tissue preservation by pyrite does not preserve as much detail as preservation in a phosphate matrix.

Degree of pyritization (DOP)

A widely used proxy for paleo-oxygenation, DOP is defined (Raiswell et al., 1988; Raiswell and Canfield, 1998) as

$$\text{DOP} = \text{pyrite Fe} / (\text{pyrite Fe} + \text{"reactive iron"})$$

Iron Sulfide Formation, Figure 10 SEM images of microbial remains preserved in early diagenetic coated iron sulfide grains (ooids and oncoids) from the Ordovician Winnipeg Formation, Saskatchewan, Canada (from Schieber and Riciputi, 2005). (a) Filamentous structure (*white arrows*) in slightly etched iron sulfide cortex. Note multiple filaments in the upper part of the picture. In the uppermost part of the picture the filaments merge into a sheet-like structure, potentially remnant of a biofilm. (b) Typical recrystallized appearance of an outermost cortex surface (unetched). Most crystals are pyrite octahedra. Between these crystal pavements one finds remnant patches of an earlier surface ((c), unetched). The latter has a lumpy appearance and consists of tightly packed clusters (a few microns in size) of iron sulfide grains. Close-ups of these clusters ((d), unetched) show that they actually consist of an ovoid smooth walled structure (*black arrow*) that is overgrown by iron sulfide grains. These are interpreted as microbes that were preserved in an iron sulfide matrix. Image (e) (unetched) shows that the smooth surfaces of these ovoids are typically perforated by irregularly shaped openings ((e), *black arrows*), comparable to wall structures seen in experimentally pyritized microbes (Bubela and Cloud, 1983).

An extraction with dithionite or 1 N HCl is supposed to mimic reactive iron dissolution in reducing sediments (Canfield, 1989; Leventhal and Taylor, 1990). The highly reactive iron fraction in sediments is defined as the sum of dithionite or 1 N HCl leachable iron, and iron in acid volatile sulfides (AVS). What DOP presumably measures is the completeness of the conversion of reactive iron into pyrite via microbial sulfate reduction during early diagenesis. The underlying premise is that DOP increases as the degree of environmental oxygenation decreases. Because of the need for sufficient quantities of organic matter and reactive iron, measurements of DOP typically focus on carbonaceous mudstones. DOP values below 0.45 are considered indicative of aerobic bottom waters, and those above 0.45 are thought to mark restricted bottom water conditions. Values above 0.75 are considered to indicate anoxic or even euxinic bottom waters (Raiswell et al., 1988). However, the DOP method should not be applied uncritically, because limitations of either metabolizable organic matter or of reactive iron can lead to DOP values that are not reflective of the actual environment (as calibrated by Raiswell et al., 1988). Several other constraints on DOP application, such as outcrop weathering, maturation, and age of rock are summarized by Raiswell et al. (1988).

DOP as an environmental indicator can also be invalidated as a consequence of sedimentary processes. Any reworking and winnowing of pyrite bearing sediments will increase the pyrite content of the sediment, without simultaneously raising the reactive iron content, and as a result the DOP can rise simply as a result of wave or current reworking. In mudstones, indications of reworking at the mm to cm scale will often go undetected (Figure 11), and can lead to inflated DOP values that are incompatible with the levels of oxygen restriction suggested by observations of frequent reworking and bioturbation (Schieber, 2001, 2003).

Marcasite and its implications

Background on marcasite

Reports of marcasite in terrigenous clastics are mainly associated with coal deposits (e.g., Nayar, 1946; Read and Cook, 1969; Wiese et al., 1987). Marcasite occurs either in the coal seams themselves, or in the roof shales, prompting Krumbein and Garrels (1952) to propose an acidic bog/peat association as the characteristic environment for marcasite formation. There have, however, been a sufficient number of diagenetic marcasite occurrences reported from normal marine sediments (e.g., Maynard and Lauffenburger, 1978; Rykart, 1983; Jowett et al., 1991; Schieber, 2002b, 2007), as well examples of marcasite that has inverted to pyrite (e.g., Bannister, 1932; Van Horn and Van Horn, 1933), to suggest that it might be more widespread in the marine realm than commonly appreciated. If this is in fact the case, and if acidic conditions are indeed a basic requirement for marcasite formation, we have an obvious problem to reconcile these

basic realities with our current understanding of early diagenesis of marine sediments.

As pointed out above, the paragenetic relationships between sedimentary iron sulfide minerals are still poorly understood (Rickard and Morse, 2005). An essential guidepost for thinking about marcasite in sedimentary environments have been experiments conducted by Murowchick and Barnes (1986) that showed that marcasite is the dominant iron disulfide below pH 5. These experiments are consistent with results from much earlier work by Allen et al. (1914) and are also consistent with subsequent work by Schoonen and Barnes (1991a, b) and Benning et al. (2000). Thus, the relative abundance of pyrite versus marcasite in sediments should be a function of pH. Because marine waters have a slightly alkaline pH of approximately 8, it has been presumed that marcasite cannot form in marine sediments during early diagenesis (e.g., Rickard et al., 1995). Yet, regardless of this, early diagenetic marcasite unquestionably occurs in marine sedimentary rocks (Maynard and Lauffenburger, 1978; Siesser, 1978; Rykart, 1983; Jowett et al., 1991; Schieber, 2002b; Schieber and Riciputi, 2005; Williams et al., 2003).

Detecting marcasite

Characteristic morphologies, such as “spearhead” twins and “cockscorn” crystals can be used to identify marcasite. However, morphology does not tell us whether the

marcasite has inverted to pyrite and the approach does not work for dense masses of crystals. As long as crystallites are large enough, it is comparatively easy to differentiate marcasite from pyrite with a petrographic microscope in reflected light mode (Ramdohr, 1975), and it is also possible to detect marcasite that has inverted to pyrite (Murowchick, 1992). For micron scale grains a new technique, “electron backscatter diffraction” (EBSD), can be applied for identification with an electron microscope. EBSD allows phase identification of submicron mineral grains and is widely used in material sciences (Prior et al., 1999; Schwartz et al., 2000).

Marcasite in sedimentary rocks

Marcasite is probably much more widespread in marine clastics than commonly assumed. It occurs as a cement mineral in marine lag deposits associated with sequence boundaries, in condensed intervals, and even in shales. Lag deposits with marcasite occur, for example, in Late Devonian shale successions of the eastern USA (Schieber, 2007). The Late Devonian Chattanooga and New Albany Shale successions contain laterally continuous erosion surfaces that compartmentalize this black shale succession into a stack of depositional sequences (Schieber, 1998a, b; Schieber and Lazar, 2004). These erosion surfaces imply substantial erosion and winnowing of previously deposited black shale during low stands of sea level (Schieber and Riciputi, 2004). The associated lag deposits contain

fish bone debris, conodonts, *Lingula* shells, quartz grains, and abundant pyrite in the form of reworked concretions and form conspicuous rust stained horizons in outcrop (Figure 12a).

In polished thin section pore filling iron sulfides show typical marcasite morphology (Figure 12b). Overall, these lags may contain 30–40% iron sulfides by volume. Loose packing of framework grains indicates precompaction cementation with marcasite. Detrital pyrite grains in these lags are often variably rounded due to mechanical reworking and show etch and corrosion pits on the surface of detrital pyrite grains that are in turn infilled and overgrown by marcasite (Schieber, 2007).

Terrigenous clastic sediments contain at best a few percent reactive iron in the form of iron oxyhydroxide coatings on terrigenous grains (Carroll, 1958; Berner, 1969). Thus, the high iron concentrations in lag deposits with up to 40% iron sulfide require a mechanism for iron enrichment, and in the Phanerozoic at least the iron was most likely reworked from underlying strata (see above). In essence, sedimentary pyrite grains need to be eroded and winnowed in order to add more iron to the surficial layer, a process favored by stratigraphic condensation when net sedimentation rates are negative (Schieber and Riciputi, 2005; Schieber, 2007).

After mechanical enrichment, however, a portion of the sulfide iron has to be remobilized to form the observed overgrowths and pore-fill cements. Preexisting grains are destroyed, either wholly or partially, in order to supply dissolved (Fe^{2+}) or readily soluble iron (e.g., $\text{Fe}(\text{OH})_3$) for the growth of new iron sulfides. Corrosion features on reworked iron sulfide grains (Schieber and Riciputi, 2005; Schieber, 2007) are evidence for iron sulfide destruction according to the following reaction:

This reaction produces acidity and dissolved ferrous iron. Further oxidation of iron (see following equation) produces iron hydroxide and further acidity.

The newly formed iron hydroxides are likely to coat surface sediment grains and would remain in the surficial sediment layer. The associated lowering of pore water pH also promotes large pore water concentrations of Fe^{2+} (Maynard, 1983). Such a setting favors reprecipitation of marcasite in the presence of H_2S influx from underlying sediments (Murowchick and Barnes, 1986; Schoonen and Barnes, 1991a, b; Benning et al., 2000).

For sandy lags the presence of marcasite and partial dissolution of reworked pyrite grains are probably a good indicator that a “reoxidation” model for marcasite formation is applicable (Schieber and Riciputi, 2005; Schieber, 2007). In shales with abundant pyrite a comparable sequence of events may be caused by downward oxidation of previously deposited muds. Potential examples are stratiform horizons of iron sulfide concretions in black shale successions (Figure 13). Where these nodule horizons occur, a gray shale bed is typically found just above them (Figure 13a), and the concretions have a flattened radial fibrous habit, a morphology suggestive of marcasite (Figure 13b).

Reoxidation of reducing organic and iron sulfide-rich sediments, also termed “burndown,” has been studied extensively in the context of Quaternary Mediterranean sapropels (e.g., Jung et al., 1997), and marcasite in shales can potentially be used as a mineral-based indicator of burndown events.

Although the generally finer grain size of diagenetic minerals in shales makes recognition of marcasite more difficult, EBSD analysis allows very tiny (micron-size)

Iron Sulfide Formation, Figure 12 Iron sulfide bearing lag deposits. (a) At left, an exposure of a sequence boundary lag (between arrows) in the late Devonian New Albany Shale. The lag is cemented by iron sulfides. Hammer for scale. (b) At right, a pore space in the lag with acicular “spearhead” twins, typical of marcasite. Electron backscatter diffraction (EBSD) analysis showed that many of the pore-fill iron sulfides still consist largely of marcasite.

Iron Sulfide Formation, Figure 13 Marcasite in late Devonian New Albany Shale, Kentucky, USA. (a) Stratiform horizon of marcasitic nodules (*white arrows*, black vs. gray shales marked by color bar at *right*). The nodules are located about 15 mm below the gray/black shale contact. The large amounts of iron sulfide accumulation at this level suggest that the redox interface stayed in that position for a long time, probably a reflection of zero to very low sedimentation. (b) Close-up of nodules that are broken through and show rims (*white arrows*) of radiating bladed marcasite (*large arrow M*). Note differential compaction.

Iron Sulfide Formation, Figure 14 SEM photomicrographs (backscatter mode) of marcasite in an iron sulfide-enriched lamina in the Cleveland Shale (Upper Devonian, NE Kentucky). (a) Clusters of bladed marcasite grains that form bedding parallel lamina. Note differential compaction around marcasite clusters, suggesting formation when the sediment still had water content in excess of 80%. It also suggests that marcasite in the Cleveland Shale formed within 10–20 cm of the sediment–water interface. (b) Close-up that shows the platy habit of marcasite crystals (marcasite identification with EBSD). The reoxidation that is implicit in this observation contradicts earlier interpretations of this shale as euxinic (e.g., Jaminski et al., 1998; Rimmer, 2004).

marcasite grains to be identified *in situ*. A preliminary application of this technique to shales has detected marcasite in carbonaceous shales that range from Ordovician to Cretaceous in age (Figures 14 and 15).

Unique fossil beds where preservation in pyrite and marcasite has been observed, such as Beecher's trilobite bed (Cisne, 1973) and pyritized ammonoids (Hudson, 1982; Seilacher et al., 1985), are another phenomenon where our "burndown" model could find application. The large stratiform iron buildup that at least some of these deposits represent requires a similar level of stratigraphic condensation as seen in some of the examples above.

Furthermore, iron needs to be mobile to form the observed mineralized and encrusted fossils. Thus, finding marcasite and dissolution features on reworked pyrite grains in pyritic Lagerstätten would support the view that such deposits may have formed during intermittent reoxygenation events.

The pH drop associated with pyrite oxidation during intermittent reoxygenation also explains textural features observed in association with iron sulfide replacement of calcareous shells. Examination of calcareous shell replacement in Carboniferous through Cretaceous mudstones showed marcasite as a common component,

Iron Sulfide Formation, Figure 15 Pyrite polyframboid cluster in Chattanooga Shale (Tennessee, USA) that formed within an algal cyst (*dark rim*). The infill was examined with EBSD. Marcasite (m) and quartz (Q) grew in the spaces between pyrite framboids (p). The open arrangement of framboids and the differential compaction around the cyst indicate that cementation happened prior to compaction. The marcasite observed here may well have been caused by intermittent pyrite oxidation in surface sediments. The relief in this image is an artifact, a consequence of oblique imaging (70° tilt) in EBSD mode.

Iron Sulfide Formation, Figure 16 SEM photomicrographs (backscatter) of marcasite replacing biogenic calcite. (a) Clam shell in Boquillas Formation (Cenomanian of West Texas). Skeletal marcasite crystals (marked m) grow as radiating clusters and replace calcite (ca). There is also partial replacement of the shell by quartz (marked qu). (b) Brachiopod shells in Barnett Shale (Mississippian of Texas). Shell in center is replaced by marcasite (marked m) that grows as bladed and sharply pointed crystals. Equant pyrite (py) formed toward end of iron sulfide deposition. Calcite shells marked ca, and replacing quartz marked qu.

intimately associated with calcite dissolution and precipitation of diagenetic quartz (Figure 16). This mineralogical triumvirate makes chemical sense because marcasite formation requires low pH, calcite dissolves at low pH, and dissolved silica (from opaline tests) precipitates under low pH conditions.

With regard to carbonate rocks, most published reports of marcasite are from chalks (e.g., Morgan-Jones, 1977; Kelts, 1976). This marcasite is typically in nodule form, measures up to 10 cm across, and shows crystals with marcasite morphology. Nonetheless, XRD analysis frequently shows that this marcasite has inverted to pyrite. There also seems to be an association with phosphate concretions, and thus with reworking, negative net sedimentation, and geochemical “reworking” of iron, just like that observed in marcasite occurrences in sandstones and shales.

Conclusions

The geobiological significance of sedimentary iron sulfides is far reaching. Microbial sulfate reduction as a metabolic pathway is of great antiquity and dates back to at least the early Archean (3.47-Ga; Shen and Buick, 2004). From that time onward, global cycling of sulfur and carbon has been essential for controlling the amount of oxygen in the Earth’s atmosphere (Berner, 2001), and some have even speculated that the emergence of life itself is tied to sulfur chemistry on the early Earth (e.g., Russell and Hall, 1997). It also appears that in itself oxygen buildup during the Precambrian led to the evolution of increasingly complex biochemical networks among microbes and eventually even to the evolution of complex life forms (Raymond and Segrè, 2006). The iron sulfides that we find in the rock record are a substantial part of the raw data for understanding the complex interaction of life with the atmosphere and the oceans. Every bit of that record, be it in the form of isotope shifts (e.g., Goldhaber, 2003), proportions and distribution of different iron sulfides, sulfide textures, stratal distribution, enclosed and preserved micro- and macro-fossils, as well as subsequent alterations of these minerals, is valuable for understanding chemical changes that affected the biosphere on the local, global, and temporal scales.

For the rock record, the enduring product of all these processes is the iron sulfide pyrite (FeS_2). Yet, the dimorph of pyrite, marcasite, can still be recognized in sedimentary rocks as old as Proterozoic (personal observations) and probably played a much larger role than commonly appreciated. In the minds of many geologists, the presence of iron sulfides in sedimentary rocks is associated with anoxic environmental conditions. In reality, however, once iron sulfides begin to form localized concentrations, be it in the form of micron-size framboids or fist-size concretions, one can imply that oxygen must have been close by. As elaborated repeatedly above, in order to form even microscopic features like pyrite framboids, iron should be able to migrate through the pore waters, and

those conditions only occur near the redox interface that “separates” deeper sulfidic from shallower oxygenated pore waters. Fundamentally, this holds true even in the most classical anoxic-euxinic locale of all, the Black Sea. There, pyrite framboids do not form in the sulfidic bottom waters, but form again at the redox interface where these waters come in contact with oxygenated surface waters (Wilkin et al., 1996). The bulk of sedimentary iron sulfides in the rock records marks the interface between the anoxic and oxic worlds; they should not be taken as an indicator of environmentally pervasive anoxia.

Definition

Variations in the abundances of the isotopes of metals, especially transition metals, arising from physical or chemical processes that discriminate among the isotopes of a given element.

Overview

Research into isotope fractionation of transition metals, alkaline earth metals, and metalloids is advancing rapidly

as a result of analytical developments. As of this writing, fractionations have been reported for more than a dozen such elements (Figure 1). These investigations are heavily motivated by geobiological considerations. In particular, there is wide interest in the use of these new isotope systems as biosignatures and as proxies for the

Isotope Fractionation (Metal), Figure 1 Observed range of isotopic variations in modern and ancient natural samples for a selection of metals and metalloids. All values are expressed in delta notation [parts per 1,000 (‰) per atomic mass unit], normalized to average Bulk Silicate Earth (indicated by the gray vertical line). Blue diamonds indicate the average isotope composition of modern seawater, where data are available. biogeochemical cycling of metals in modern and ancient settings. This article briefly reviews the analytical issues in historical context and the state of geobiological applications.

Historical and analytical context

Investigations into natural variations in the isotope compositions of transition metals and other metallic elements began in the middle of the twentieth century (Valley and Anderson, 1947; Shields et al., 1965), in parallel with research into isotope variations of non-metals (Urey, 1947; Bigeleisen, 1965). Most of this early metal isotope research focused on variations arising from radioactive decay for geochronology, i.e., “radiogenic isotope geochemistry,” whereas non-metal isotope research was dominated by investigations of the mechanisms and applications of mass-dependent fractionation (esp. of C, O, N, and S), which came to be called “stable isotope” geochemistry.

This bifurcation was largely a consequence of the different types of mass spectrometry (MS) most readily used for these two classes of elements. Because most metals do not readily form volatile compounds, analyses of their isotope compositions were conducted primarily using thermal ionization MS (TIMS), whereby purified samples are placed on metal filaments which are heated under vacuum to form thermal ions, which are then introduced into a mass analyzer (typically, a magnetic sector). This ionization method itself induces mass-dependent isotope fractionation of a magnitude comparable to natural variations. The effects of such fractionations can be precisely corrected by external or internal normalization schemes (Wasserburg et al., 1981), but these schemes also “correct” for any natural mass-dependent fractionation. As a result, TIMS is best suited for the analysis of isotope variations arising from non-mass-dependent processes, notably radioactive decay or nucleosynthetic anomalies. Precise measurements of mass dependent isotope fractionation using TIMS are possible, but require use of double spiking procedures (Russell et al., 1978; Albarède and Beard, 2004).

In contrast, isotope variations of non-metals were (and still are) typically measured using gas source electron impact MS, taking advantage of the ease with which many of these elements are converted to gas phase compounds such as H₂O or CO₂. An electron beam can readily ionize these gases. This MS method lends itself to an analytical scheme in which gases derived from samples and standards are introduced in rapid alternation to the same instrument. Such “sample-standard bracketing,” not possible with TIMS, corrects for mass fractionation induced by the mass spectrometer without compromising the ability to detect preexisting natural isotope variations. Hence, stable isotope studies of mass-dependent effects flourished for the most abundant non-metal elements.

In the final years of the twentieth century and the first decade of the twenty-first, the development of inductively

coupled plasma source MS coupled to multiple ion “collectors” (MC-ICP-MS) made it possible to easily ionize transition metals and other elements using procedures that allowed for precise determination of mass-dependent isotope variations (Walder and Freedman, 1992; Halliday et al., 1995; Maréchal et al., 1999). Specifically, in ICP-MS samples are introduced to the mass spectrometer by nebulization of aqueous solutions into a high-energy plasma (Houk and Thompson, 1988). This technique readily ionizes most elements, and is amenable to sample-standard bracketing analogous to that employed for traditional stable isotope analyses (as well as double spiking). The combination of ICP ionization, magnetic sector mass analyzers, and multiple ion collectors, greatly increased the precision of such analyses. High mass resolution (Weyer and Schwieters, 2003), collision cells (Turner et al., 1998), and specialized nebulizers (Belshaw et al., 2000) solved analytical problems specific to particular elements such as Fe. These developments made it practical to examine physical and chemical fractionations of the isotopes of many metals (reviewed in Johnson et al., 2004a; Anbar and Rouxel, 2007; Weiss et al., 2008). This research led to the discovery that such variations are ubiquitous in nature, easily produced in the lab, and relevant to geobiological applications.

Variations in isotope ratios of these elements are typically of order 0.1–1‰, and so isotope compositions are usually reported as ‰ deviations from a reference standard, using the classic “ δ notation” (some studies report compositions as parts-per-ten-thousand deviations, using the analogous “ ϵ notation”; e.g., Zhu et al., 2000; Rouxel et al., 2003; Rehkämper et al., 2004; Lacan et al., 2006; Stirling et al., 2007). Analytical precision is now routinely $\pm 0.05\text{‰}$ or better for most elements, although reproducibility of natural samples is often not as good as that of pure standards due to complications arising from impurities even in chemically processed samples.

Biosignatures

Much of the research into metal isotope fractionation is motivated by the possibility that Fe isotopes, in particular, could prove useful as biosignatures in ancient materials. This idea builds on an analogy with carbon, nitrogen, and sulfur isotopes. These elements are fractionated as a result of biologically mediated redox chemistry, which dominates the biogeochemical cycling of these elements (e.g., Rankama, 1948; Craig, 1953b; Harrison and Thode, 1958; Kaplan and Rittenberg, 1964; Wada and Hattori, 1976a, b; Altabet and Francois, 1994; Canfield, 2001; Horita, 2005). Fe oxidation and reduction at the Earth’s surface is likewise biologically catalyzed, by the actions of dissimilatory bacteria that derive metabolic energy from redox reactions involving Fe.

Fe isotope fractionation has been documented to occur during dissimilatory reduction of Fe(III) phases such as hydrous ferric oxide and hematite by bacteria including strains of the genera *Shewanella* and *Geobacter* (Beard

et al., 1999; Crosby et al., 2007). Fe isotopes are also fractionated during oxidation of dissolved Fe(II) and precipitation of Fe(III)-oxides mediated by *Acidithiobacillus ferrooxidans* (Balci et al., 2006) and an anoxygenic photoautotroph of the genus *Thiodictyon* (Croal et al., 2004). In all cases, Fe(II) is isotopically lighter by 1.3–3‰ relative to Fe(III)-oxide (here, Fe isotope variations are reported in terms of $^{56}\text{Fe}/^{54}\text{Fe}$). A dissolved Fe isotope profile from the Southern Ocean – the first data of its kind – shows small variations between –0.13 and 0.21‰ that appear to be consistent with biological utilization and remineralization (Lacan et al., 2008).

The specific mechanisms governing these isotope effects are complex because a multitude of processes can cause Fe isotopes to fractionate, including adsorption of dissolved Fe(II) to Fe(III)-oxide surfaces (Icopini et al., 2004; Crosby et al., 2007; Jang et al., 2008), precipitation of Fe-bearing minerals (Bullen et al., 2001; Skulan et al., 2002; Wiesli et al., 2004; Butler et al., 2005), and isotope-exchange between different Fe-ligand species or ligand-promoted dissolution (Brantley et al., 2001; Schauble et al., 2001; Wiederhold et al., 2006; Dideriksen et al., 2008; Hill and Schauble, 2008; Domagal-Goldman et al., 2009), and even diffusion (Rodushkin et al., 2004). Many of these processes occur in even the simplest experiments involving dissimilatory Fe metabolizing bacteria. However, the largest effect is the equilibrium isotope fractionation between Fe(II) and Fe(III) species. Experiments (Johnson et al., 2002; Welch et al., 2003) and theory (Schauble et al., 2001; Anbar et al., 2005; Domagal-Goldman and Kubicki, 2008) indicate fractionation of 2.5–3‰ favoring light Fe in the Fe(II) species when Fe(II) and Fe(III) aquo complexes equilibrate at $\sim 25^\circ\text{C}$. These issues and their consequences are reviewed in detail elsewhere (Johnson et al., 2004b; Dauphas and Rouxel, 2006; Johnson et al., 2008a).

A key consideration, however, is that, in contrast to microbial conversion of S or C, dissimilatory Fe reduction and oxidation are extracellular processes that take place at mineral surfaces, facilitated by electron shuttles. Therefore, isotope fractionation may result from isotope exchange between surface adsorbed Fe(II) and Fe(III) at the oxide surface (Crosby et al., 2005). This hypothesis may explain why the fractionation factors during dissimilatory Fe(III) reduction and Fe(II) oxidation are so similar, independent of the species of microbe or the substrate, and why they are also within error of the equivalent fractionation factor between dissolved Fe(II) and Fe(III)-oxide in abiotic systems (Crosby et al., 2007).

Other transition metals for which isotope fractionation during biological transformation has been demonstrated experimentally include Mo (Wasylenki et al., 2007), Zn (John, 2007), Cr (Sikora et al., 2008), Ni (Cameron et al., 2009), and Hg (Bergquist and Blum, 2007; Kritee et al., 2007). Some organisms convert metal redox states to gain metabolic energy or for detoxification, or both. In such cases, isotope fractionation occurs during dissimilatory reduction or oxidation (e.g., Fe, Cr, and Hg). In other

cases, metals are fractionated during assimilation (e.g., Zn, Mo, Fe, and Ni).

Redox changes, adsorption to inorganic and organic surfaces, precipitation, ligand exchange and diffusion can occur independent of biology in aqueous systems. Therefore, the same considerations lead to widespread nonbiological Fe isotope effects in experiments and nature (e.g., Anbar et al., 2000; Bullen et al., 2001; Johnson et al., 2002; Brantley et al., 2004; Icopini et al., 2004; Butler et al., 2005; Crosby et al., 2007; Dideriksen et al., 2008), making it difficult to differentiate biogenic and abiogenic effects in natural systems. The same is true for other metals (e.g., Ellis et al., 2002; Rehkämper et al., 2002; Larson et al., 2003; Rouxel et al., 2003; Barling and Anbar, 2004; Mathur et al., 2005; Pokrovsky et al., 2005; Siebert et al., 2006a; Malinovsky et al., 2007; Stirling et al., 2007; Balistrieri et al., 2008; John et al., 2008; Vance et al., 2008). As more is learned, multi-element isotope fractionation patterns might be developed that constitute distinctively biological fingerprints. However, as of now no definitive metal isotope “magic bullet” biosignature has been identified.

In this regard the isotopes of Fe and other metals are no different than the C and S isotope systems. For these elements, too, abiotic effects are potentially significant (Ohmoto and Rye, 1979; Chang et al., 1983; Machel et al., 1995; Horita and Berndt, 1999; Pavlov et al., 2001; McCollom and Seewald, 2006). As a result, controversy erupts whenever isotope values alone, absent other context, are used as evidence of life (Rankama, 1950; Craig, 1953a; Schidlowski, 1988; Mojzsis et al., 1996; Schidlowski, 2001; van Zuilen et al., 2002). Nevertheless, these non-metal isotope systems are widely used to build logical, if not definitive, arguments about biological influence over C and S cycling in modern and ancient environments (Goldhaber and Kaplan, 1980; Canfield and Teske, 1996; Rosing, 1999; Shanks, 2001; Shen and Buick, 2004; Hinrichs et al., 2006). Similarly, for Fe and other metals. For example, it has been proposed that isotopically light Fe isotope values observed in anoxic sediment pore fluids are indicative of the importance of bacterial dissimilatory Fe reduction in such settings (Bergquist and Boyle, 2006; Severmann et al., 2006). Hence, $\delta^{56}\text{Fe}$ measurements in rocks derived from ancient anoxic sediments may provide information about the evolution of this metabolism (Johnson et al., 2008a). Such applications are discussed below.

Biogeochemistry and paleoenvironmental proxies

In addition to their growing use in biosignature research, metal stable isotopes are evolving into powerful proxies of biogeochemical cycling and paleoenvironmental conditions (Anbar and Rouxel, 2007; Johnson et al., 2008a). Most of this research centers on paleoredox applications, particularly on understanding changes in ocean oxygenation in response to rising atmospheric O_2 before the Cenozoic era – a topic of intense interest to geobiologists.

Initial efforts have emphasized isotopes of Fe and Mo. These elements are both found at the Earth's surface in two or more redox states, and the geochemical behaviors of both elements are strongly affected by the prevailing redox conditions encountered in the environment. For example, a recent study of the Black Sea indicates that bulk sedimentary Fe isotope compositions are related to the availability of dissolved O_2 and the presence of H_2S in the water column (Severmann et al., 2008). Apparently, an isotopically distinct pool of Fe(II) is generated during early diagenetic processes, including dissimilatory Fe reduction of Fe(III) oxides, in sediment pore waters on basin shelves. If the water column is anoxic, this isotopically distinct Fe can migrate to the deeper basin, where it is immobilized in H_2S -rich waters as pyrite. Isotopically light pyrite therefore can provide a paleorecord of basin anoxia and dissimilatory Fe metabolism. Similar systematic Fe isotope variations have been observed in the sediments of other modern (Fehr et al., 2008) and ancient (Czaja et al., 2010; Duan et al., 2010) anoxic depositional settings. Hence, under certain conditions the Fe isotope compositions in ancient sediments record evidence of ancient redox conditions.

This concept has been applied to the interpretation of systematic changes in sedimentary $\delta^{56}Fe$ through time (Matthews et al., 2004; Rouxel et al., 2005; Yamaguchi et al., 2005; Archer and Vance, 2006; Jenkyns et al., 2007). In Archean black shales dating to at least 3 Ga, Fe isotope values of -1 to -3‰ relative to average igneous rocks are common (e.g., Rouxel et al., 2005; Yamaguchi et al., 2005; Archer and Vance, 2006); variations among igneous rocks and minerals are much smaller; e.g., Beard and Johnson, 2004; Williams et al., 2005; Poitrasson, 2006; Weyer et al., 2007; Teng et al., 2008). After ~ 1.8 Ga, fractionation in such sediments is negligible (Rouxel et al., 2005). These values may reflect the importance of dissimilatory Fe reduction in marine sediments as a source of dissolved Fe(II) to Archean ocean basins (Yamaguchi et al., 2005; Johnson et al., 2008b; Severmann et al., 2008; Czaja et al., 2010 but see also Rouxel et al., 2005). If so, they provide strong evidence that this metabolism was important in Archean oceans, consistent with the notion that the deep oceans at that time were anoxic and that Fe(III) was being produced in surface oceans and delivered to sediments (e.g., Walker, 1987; Kappler et al., 2005; Konhauser et al., 2005).

The production of Fe(III) may itself be biologically catalyzed (Walker, 1987; Kappler et al., 2005; Konhauser et al., 2005), and so it has been hypothesized that Precambrian Banded Iron Formations (BIFs) are manifestation of biogenic Fe(II) oxidation. So far it has not been possible to identify a unique organic biomarker for microbial Fe(II) oxidation in the rock record, which is why hopes are high for Fe isotopes to confirm a biogenic origin of BIFs (Yamaguchi et al., 2005; Johnson et al., 2008b). However, given the complexity of the often overlapping biotic and abiotic fractionations, it remains doubtful that Fe isotope evidence on its own will be able to deliver such

a “smoking gun” (see discussion in Rouxel et al., 2006b; Yamaguchi and Ohmoto, 2006). Instead, Dauphas et al. (2004) have used Fe isotopes to make the case that the controversial early Archean Akilia Island rocks are indeed metamorphosed chemical precipitates (possibly biogenic) rather than a heavily metamorphosed igneous protolith (Fedo and Whitehouse, 2002).

Although, Mo isotopes, like Fe, presumably fractionate during Mo reduction or oxidation, this is paradoxically not the basis of the use of Mo isotopes as a redox proxy. Instead, Mo isotope paleoredox applications follow from the large isotope fractionation that occurs when Mo adsorbs to some oxide mineral surfaces. The best-studied effect, seen in natural samples and laboratory experiments, occurs on the surfaces of birnessite and other Mn oxyhydroxides. A fractionation of $\sim 2.7\text{‰}$ is observed in $^{98}Mo/^{95}Mo$ ratios, favoring adsorption of light Mo isotopes (Barling and Anbar, 2004) that seems largely independent of temperature or solution composition (Wasylenski et al., 2008c). The origin of this surprisingly large effect remains under investigation (Tossell, 2005; Weeks et al., 2007; Wasylenski et al., 2008b). A fractionation approximately half as large is seen during adsorption to ferric oxyhydroxides (Canfield et al., 2008; Wasylenski et al., 2008a).

In contrast, Mo isotope fractionation is muted during removal into sediments accumulating under euxinic (H_2S -rich) bottom waters. This finding probably reflects near-quantitative scavenging of Mo when the concentration of H_2S exceeds $\sim 10 \mu M$ (Helz et al., 1996); sediments accumulating under conditions that are anoxic but not sulfidic exhibit modest isotope fractionation (Poulson et al., 2006; Neubert et al., 2008), as do suboxic sediments (McManus et al., 2002; Siebert et al., 2006b). In both cases, light isotopes are preferentially removed.

The net result of these processes is that $\delta^{98/95}Mo$ of seawater – in which the residence time of Mo today exceeds 500,000 year – reflects the balance between oxic and reducing sedimentary sinks. Today, most Mo is removed to oxic and suboxic sedimentary sinks, shifting the dissolved Mo pool in the oceans to heavy values as compared to riverine and other inputs (Barling et al., 2001; Siebert et al., 2003); $\delta^{98/95}Mo$ of the modern oceans is $\sim 2.4\text{‰}$ vs. an assumed continental crust value of $\sim 0\text{‰}$ and rivers carrying Mo with an average isotopic composition of $\sim 0.7\text{‰}$ (Archer and Vance, 2008). The balance of fluxes in ancient, less oxygenated oceans would have been shifted toward euxinic and suboxic sinks that cause less fractionation than Mn oxides. Hence, Mo in such oceans would be lighter than today. Ancient ocean $\delta^{98/95}Mo$ can be reconstructed from measurements in black shales (Barling et al., 2001; Siebert et al., 2003), so long as care is taken to ensure that conditions were locally euxinic during deposition (Gordon et al., 2008; Neubert et al., 2008). This concept has been used to examine the extent of ocean anoxia in the Archean and Paleoproterozoic (Siebert et al., 2005; Wille et al., 2007),

mid-Proterozoic (Arnold et al., 2004), early Cambrian (Wille et al., 2008), and Jurassic (Pearce et al., 2008).

Building on these successful examples, other transition metal isotope systems are being explored for paleoenvironmental possibilities. These include U and Th isotopes (Rehkämper et al., 2004; Weyer et al., 2008), which are like Mo in that they fractionate during adsorption to metal oxides but are driven by an unusual fractionation mechanism based on differences in nuclear volume rather than mass (Schauble, 2007). Other novel isotope systems that are currently being explored include (Miller et al., 2008), Cr (Amor et al., 2008; Frei and Gaucher, 2008), and Ce (Weber et al., 2008).

In addition to transition metals, there has been a surge of activity examining the mass-dependent isotope variations of alkaline earth metals, including Mg (Young and Galy, 2004; Tipper et al., 2006) and Ca (Skulan et al., 1997; De La Rocha and DePaolo, 2000; Nägler et al., 2000) and a number of metalloids such as B (Pearson and Palmer, 1999; Pearson and Palmer, 2000; Hönisch and Hemming, 2005; Pagani et al., 2005), Si (De La Rocha et al., 1998; Varela et al., 2004; Reynolds et al., 2006), Ge (Rouxel et al., 2006a; Siebert et al., 2006a), and Sb (Rouxel et al., 2003). Most of this research is focused on paleoenvironmental questions of direct interest to geobiologists. In several cases, the isotope compositions are measured in materials, such as carbonates, phosphates, or silica, of biogenic origin.

Finally, many of these isotope systems are also being used to unravel issues in modern biogeochemical cycling. In some cases such research is an essential foundation for paleoenvironmental applications, since isotope variations in ancient sediments cannot be interpreted without an understanding of processes that are best studied and calibrated in modern settings. However, in at least one case modern applications are the primary motivation: Hg. This new isotope system is characterized by surprisingly large fractionations up to 2.5‰ (in terms of $^{199}\text{Hg}/^{198}\text{Hg}$) that are strikingly non-mass-dependent (Bergquist and Blum, 2007). Hg isotopes are finding their initial applications as a tool to shed light on Hg sources (Foucher and Hintelmann, 2006), on microbially mediated transformations of Hg in the environment (Kritee et al., 2007), and on the mechanisms of Hg bioaccumulation in food chains (Bergquist and Blum, 2007). It is likely that more isotope systems will find similar uses in modern settings, such as to trace sources of bioessential elements to the oceans (Severmann et al., 2006), or terrestrial environments (Borrok et al., 2008; Chen et al., 2008; Gioia et al., 2008), or to understand the pathways of uptake of these elements by microbiota in nature (Cameron et al., 2009; John, 2007; Wasylenki et al., 2007).

Summary

Technological advances in MS have led to the emergence of a new subdiscipline in the field of stable isotope geochemistry over the past decade: natural variations in

isotope compositions have now been shown to occur for many metals that were previously very difficult or impossible to measure with sufficient precision and accuracy. Isotope fractionations have been linked to a wide range of processes, including biological utilization (dissimilatory and assimilatory), surface adsorption, redox-exchange, mineral precipitation, ligand exchange, or diffusion. A clear distinction between biological and abiotic processes based on metal isotope variations alone is often not possible, because both processes may result in isotope fractionations of similar magnitude, and may occur simultaneously. This apparent complication can be resolved by integrating these novel proxies with more traditional proxies that can provide context for their interpretation. The two isotope systems that have so far received the most attention are Fe and Mo, and this contribution briefly reviews examples of their application in biogeochemical or paleoenvironmental research.

ISOTOPES AND GEOBIOLOGY

Jochen Hoefs
University of Göttingen, Göttingen, Germany

Definition

It has long been recognized (e.g., Thode et al. (1949), Craig (1953) and Wellman et al. (1968)) that biological processes significantly fractionate the isotopes of C, N, and S, leading to characteristic *biosignatures* in sedimentary rocks that will be more or less preserved in the geological record. In the following, a brief overview is given of the major isotope fractionation processes in the biosphere and the geosphere. Special attention will be paid to secondary bacterial activity after deposition of the organic matter. Questions of general interest are isotopic indicators of early life on Earth and on Mars. A note of caution, however, is given whether abiogenic processes may lead to isotope compositions similar to that of biological activity.

Carbon isotope fractionation during photosynthesis

Early reviews by O’Leary (1981) and Farquhar et al. (1989) have provided the biochemical background of carbon isotope fractionations during photosynthesis, with more recent accounts by Hayes (2001) and Freeman (2001). The main isotope-discriminating steps during biological carbon fixation are (1) the uptake and intracellular diffusion of CO_2 and (2) the biosynthesis of cellular components. Such a two-step model was first proposed by Park and Epstein (1960):

From this simplified scheme, it follows that the diffusional process is reversible, whereas the enzymatic carbon fixation is irreversible. The two-step model of carbon fixation clearly suggests that isotope fractionation is dependent on the partial pressure of CO_2 , i.e., $p\text{CO}_2$ of the system. With an unlimited amount of CO_2 available to a plant, the enzymatic fractionation will determine the isotopic difference between the inorganic carbon source and the final bioproduct. Under these conditions, ^{13}C fractionations may vary from -17 to -40‰ (O’Leary, 1981). When the concentration of CO_2 is the limiting factor, the diffusion of CO_2 into the plant is the slow step in the reaction and carbon isotope fractionation of the plant decreases.

CO₂ is directly converted by the enzyme ribulose biphosphate carboxylase/oxygenase (“Rubisco”) to a 6-carbon molecule that is then cleaved into two molecules of phosphoglycerate (PGA), each with three carbon atoms (plants using this photosynthetic pathway are, therefore, called C₃ plants). Most PGA is recycled to make ribulose biphosphate, but some are used to make carbohydrates. Free exchange between external and mesophyll CO₂ makes the carbon fixation process less efficient, which causes the observed large ¹³C depletions of C₃ plants.

C₄ plants incorporate CO₂ by the carboxylation of phosphoenolpyruvate (PEP) via the enzyme PEP carboxylase to make the molecule oxaloacetate, which has four carbon atoms (hence C₄). The carboxylation product is transported from the outer layer of mesophyll cells to the inner layer of bundle sheath cells, which are able to concentrate CO₂, so that most of the CO₂ is fixed with relatively little carbon fractionation. Because mesophyll cells are permeable and bundle sheath cells are less permeable, C₃ versus C₄ plants have ¹³C depletions of −18‰ versus −4‰ relative to atmospheric CO₂. Even more complex is C-isotope fractionation in aquatic plants. Factors that control the ¹³C of phytoplankton include temperature, availability of CO₂ (aq), light intensity, nutrient availability, pH, and physiological factors such as cell size and growth rate.

Since the pioneering work of Park and Epstein (1960) and Abelson and Hoering (1961) it is well known that ¹³C is not uniformly distributed among the total organic matter of plant material, but varies between carbohydrates, proteins, and lipids. The latter class of compounds is considerably depleted in ¹³C relative to the other products of biosynthesis. Although the causes of these ¹³C differences are not entirely clear, kinetic isotope effects seem to be more plausible than thermodynamic equilibrium effects.

Organic matter in the geosphere is a complex mixture of source organisms having variable biosynthetic pathways and detrital remains. The determination of ^{δ¹³C} values of bulk organic matter is thus unable to distinguish among the different carbon sources. Immediately after burial of the biological organic material into sediments, complex diagenetic changes occur in the organic matter. Two processes have been proposed to explain the observed changes in carbon isotope composition: (1) preferential degradation of organic compounds which have different isotope composition compared to the preserved organic compounds. Since easily degradable organic compounds such as amino acids are enriched in ¹³C compared to the more resistant compounds such as lipids, degradation causes a shift to slightly more negative ^δ values. (2) Isotope fractionations due to metabolism of microorganisms produce new compounds having different isotopic compositions than the original source material. A classic example has been presented by Freeman et al. (1990) analyzing hydrocarbons from the Messel

Isotopes and Geobiology, Table 1 ^{δ¹³C} values of separated individual hydrocarbons (biomarkers) from the Messel shale (Freeman et al., 1990)

Peak	^{δ¹³C} (‰)	Compound
1	−22.7	Norpristane
2	−30.2	C ₁₉ acyclic isoprenoid
3	−25.4	Pristane
4	−31.8	Phytane
5	−29.1	C ₂₃ acyclic isoprenoid
8	−73.4	C ₃₂ acyclic isoprenoid
9	−24.2	Isoprenoid alkane
10	−49.9	22,29,30-Trisnorhopane
11	−60.4	Isoprenoid alkane
15	−65.3	30-Norhopane
19	−20.9	Lycopane

shale in Germany (see Table 1). While the major portion of the analyzed hydrocarbons reflects the primary biological source material, some hydrocarbons having low concentrations are extremely ¹³C depleted indicating their secondary microbial origin in a methane-rich environment. Later studies, summarized by Peckmann and Thiel (2004), have documented even larger ¹³C depletions (^{δ¹³C} values as low as −120‰) in various biomarkers that have been formed by diverse methanotrophic taxa.

C-isotope evidence for earliest signs of life on Earth

The idea of using C-isotope compositions of organic matter for the detection of early life dates back to the classic paper of Craig (1953). Already, at that time, it was discussed whether graphitic carbon in old rocks could be identified as being of biogenic origin (Craig, 1954; Rankama, 1954). This controversy about the meaning of graphite ^{δ¹³C} values from early Archean (3.5–3.8 Ga) rocks has continued till today (e.g., Bolhar et al., 2004). The validity of using carbon isotopes in the search for early life hinges on the assumption that early organic metabolism produced a C-isotope fractionation effect similar to that observed today. In addition, the thermal history of the metasediments has to be considered. In early Archean metasedimentary rocks from Greenland, ^{δ¹³C} values range from −22 to −50‰, which could be interpreted as biogenic (Mojzsis et al., 1996). Very negative values were measured for tiny particles of reduced carbon within apatite grains, which apparently had been shielded from metamorphic alteration. However, a case also can be made that graphite from Archean rocks may be of abiotic, hydrothermal origin. In recent years, more experimental and natural evidence has been presented that Fischer–Tropsch type reactions may produce abiogenic organic matter with ^{δ¹³C} values similar to biogenic organic matter (Taran et al., 2007).

Nitrogen

Microorganisms are responsible for all major conversions in the biological nitrogen cycle, which generally is divided into nitrogen fixation, nitrification, and denitrification. Other bacteria return nitrogen to the atmosphere as N_2 . *Fixation* describes the conversion of unreactive atmospheric N_2 into reactive nitrogen such as ammonium, usually involving bacteria. Fixation commonly produces organic materials with $\delta^{15}N$ values slightly less than 0‰ ranging from −3 to +1 (Fogel and Cifuentes, 1993) and is performed in the roots of plants by many bacteria. The large amount of energy needed to break the molecular nitrogen bond makes nitrogen fixation a very inefficient process with little associated N-isotope fractionation.

Nitrification is a multistep oxidation process mediated by several different autotrophic organisms. Nitrate is not the only product of nitrification, different reactions produce various nitrogen oxides as intermediate species. Nitrification can be described as two partial oxidation reactions, each of which proceeds separately. Oxidation by *Nitrosomonas* ($NH_4 \rightarrow NO_2$) followed by oxidation by *Nitrobacter* ($NO_2 \rightarrow NO_3$). Because the oxidation of nitrite to nitrate is generally rapid, most of the N-isotope fractionation is caused by the slow oxidation of ammonium by *Nitrosomonas*. In N-limited systems, fractionation is minimal.

Denitrification (reduction of more oxidized forms to more reduced forms of nitrogen) is a multistep process with various nitrogen oxides as intermediate compounds resulting from biologically mediated reduction of nitrate. Denitrification takes place in poorly aerated soil and in stratified anaerobic water bodies. Denitrification causes the $\delta^{15}N$ values of the residual nitrate to increase exponentially as nitrate concentrations decrease. Experimental investigations have demonstrated that fractionation factors may change from 10‰ to 30‰, with the largest values obtained under lowest reduction rates. Table 2, which gives a summary of observed N-isotope fractionations, clearly indicates the dependence of fractionation factors on nitrogen concentrations and demonstrates that

Isotopes and Geobiology, Table 2 Naturally observed isotope fractionation for nitrogen assimilation (after Fogel and Cifuentes, 1993)

N_2 fixation	−3 to +1‰
NH_4^+ assimilation	
Cultures	
Millimolar concentrations	0 to −15‰
Micromolar concentrations	−3 to −27‰
Field observations	
Micromolar concentrations	−10‰
NO_3^- assimilation	
Cultures	
Millimolar concentrations	0 to −24‰
Micromolar concentrations	−10‰
Field observations	
Micromolar concentrations	−4 to −5‰

at low nitrogen concentrations, fractionation is nearly zero because virtually all the nitrogen is used.

Sulfur-dissimilatory sulfate reduction

Large ^{34}S -isotope fractionations are induced during bacterial sulfate reduction. Since the early work with living cultures (Harrison and Thode, 1957a, b) it is well known that sulfate-reducing bacteria produce sulfide depleted in ^{34}S by 4–49‰. In general, the rate-limiting step is the breaking of the first S–O bond, namely the reduction of sulfate to sulfite (Goldhaber and Kaplan, 1974; Brunner et al., 2005).

Despite decades of intense research, the factors that determine the magnitude of sulfur isotope fractionation during bacterial sulfate reduction are still under debate. The magnitude of isotope fractionation depends on the rate of sulfate reduction with the highest fractionation at low rates and the lowest fractionation at high rates. One parameter which remains unclear is sulfate concentration.

Naturally occurring sulfides in sediments and euxinic waters are commonly depleted in ^{34}S by up to 70‰, far beyond the apparent capabilities of sulfate-reducing bacteria in the laboratory. Much of the sulfide produced by sulfate reduction in sediments is reoxidized, often via compounds in which sulfur has intermediate oxidation states that do not accumulate, but are readily transformed and can be further disproportionated by bacteria.

Another factor that is of great importance for the observed sulfur isotope variations of natural sulfides is whether sulfate reduction takes place in an open or a closed system. An “open” system has an infinite reservoir of sulfate in which continuous removal from the

Isotopes and Geobiology, Figure 1 Rayleigh plot for sulfur isotope fractionation during closed-system reduction of sulfate. Assumed fractionation factor 1.025; assumed initial isotope composition of sulfate +10‰.

source produces no detectable loss of material. Typical examples are the Black Sea and local oceanic deeps. In such cases, H_2S is extremely depleted in ^{34}S while consumption and change in ^{34}S remain negligible for the sulfate. In a “closed” system, the preferential loss of the lighter isotope ^{32}S from the reservoir has a feedback on the isotopic composition of the unreacted source material. The changes in the ^{34}S content of residual sulfate and of the H_2S are modeled in Figure 1, which shows that $\delta^{34}\text{S}$ values of the residual sulfate steadily increase with sulfate consumption (a linear relationship on a log-normal plot). The curve for the derivative H_2S is parallel to the sulfate curve at a distance which depends on the magnitude of the fractionation factor. As shown in Figure 1, H_2S may become isotopically heavier than the original sulfate when about two third of the reservoir has been consumed. The $\delta^{34}\text{S}$ curve for “total” sulfide asymptotically approaches the initial value of the original sulfate. It should be noted, however, that apparent “closed-system” behavior of covarying sulfate and sulfide $\delta^{34}\text{S}$ values might be also explained by “open-system” differential diffusion of the different sulfur isotope species (Jørgensen et al., 2004).

Another characteristic feature of microbial sulfate reduction is significant small-scale spatial variability in S-isotope composition of pyrite. Up to 105‰ variations in $^{34}\text{S}/^{32}\text{S}$ ratios within strongly zoned pyrite was observed by McKibben and Riciputi (1998). This zonation arises from progressive precipitation of sulfide from pore water sulfate enriched in ^{34}S providing more ^{34}S -enriched sulfide.

New insights on sulfur isotope fractionation mechanisms have been obtained from the analysis of the minor isotopes ^{33}S and ^{36}S (Farquhar et al., 2003; Johnston et al., 2005; Ono et al., 2006). By studying all sulfur isotopes with very high precision, these authors could demonstrate that bacterial sulfate reduction follows a mass-dependent relationship that is slightly different from that expected by equilibrium fractionations. As a result, samples with the same $\delta^{34}\text{S}$ value can have different $\Delta^{33}\text{S}$ and $\Delta^{36}\text{S}$ values. This opens the possibility to distinguish between different fractionation mechanisms and biosynthetic pathways (Ono et al., 2006). For instance, bacterial sulfate reduction shows slightly different fractionation relationships compared to sulfur disproportionation reactions (Johnston et al., 2005).

When did bacterial sulfate reduction start on Earth?

Considering a typical difference in $\delta^{34}\text{S}$ values of 20–60‰ between marine sulfate and bacteriogenic sulfide in present-day sedimentary environments, similar fractionations in ancient sedimentary rocks may be interpreted as an evidence for the activity of sulfate-reducing bacteria. The presence or absence of such fractionations in sedimentary rocks thus may constrain the time of emergence of sulfate-reducing bacteria. Sedimentary pyrite depleted in ^{34}S has been observed as far back in geological time as the Precambrian. There is, however,

debate about the dating of first onset of bacterial reduction in the geological record.

In early Archean sedimentary rocks, most sulfides and the rare sulfates have $\delta^{34}\text{S}$ values near 0‰ (Monster et al., 1979; Cameron, 1982), which has been interpreted as indicating an absence of bacterial reduction in the Archean. Shen et al. (2001) and Shen and Buick (2004) argued that the large spread in $\delta^{34}\text{S}$ values of microscopic pyrites aligned along growth faces of former gypsum in the 3.47 Ga North Pole barite deposit; Australia represents the oldest evidence for microbial sulfate reduction. By measuring all four stable isotopes ^{32}S , ^{33}S , ^{34}S , and ^{36}S , additional evidence can be gained to decouple hydrothermal versus biological processes (Ono et al., 2006) even when $\delta^{34}\text{S}$ values are inconclusive.

Mars

McKay et al. (1996) have claimed that Martian meteorite ALH 84001 – found in Antarctica – contains evidence of post-Martian life. Various kinds of apparent biosignatures with characteristic isotope compositions have been suggested: organic matter, carbonate minerals, magnetite grains, and sulfide minerals. After intensive investigations during the last years, none of these proposed biosignatures have survived as such.

Carbonates in Martian meteorites have been especially well studied because understanding the formation conditions of the carbonates is crucial in this connection. Despite extensive chemical and mineralogical studies, the environment of carbonate formation has remained unclear. For instance, in situ C-isotope analysis by Niles et al. (2005) gave highly zoned $\delta^{13}\text{C}$ values from +30‰ to +60‰ consistent with a derivation from the Martian atmosphere and suggesting abiotic formation.

Further evidence about a nonbiogenic origin of Martian carbonates (and even less abundant sulfates) has been presented by Farquhar et al. (1989). By measuring $\delta^{17}\text{O}$ and $\delta^{18}\text{O}$ values, these authors observed an ^{17}O anomaly in the carbonates relative to the silicates which they interpreted as being produced by the photochemical decomposition of ozone just as in the Earth’s stratosphere. This finding suggests that carbonates (and sulfates) are derived from atmosphere–regolith interactions on Mars and not from biological activities.

Fe isotopes as biosignatures?

Virtually all reduction from Fe^{3+} to Fe^{2+} at the Earth’s surface is mediated by the metabolism of dissimilatory bacteria. Biological processes, therefore, may produce measurable Fe-isotopic fractionations because the metabolic processing of Fe involves a number of steps such as transport across membranes that may fractionate Fe isotopes. Experiments with dissimilatory Fe-reducing bacteria of the genus *Shewanella* indicate that iron isotope fractionations are a function of Fe(III) reduction rates: at low rates the produced Fe^{2+} is isotopically depleted by 1.3‰, whereas the depletion is up to 3‰ at high rates (Johnson et al., 2005).

Iron isotope fractionation has also been observed during bacterial Fe oxidation (Croal et al., 2004). Fe(II) oxidizing phototrophs may produce under anaerobic conditions a ferrihydrite precipitate that is 1.5‰ higher than the aqueous Fe(II) source. Controversy still exists whether the iron isotope variations observed in microbial experiments are primarily controlled by kinetic or nonbiological equilibrium factors. Since abiotic iron reduction/oxidation reactions may reveal fractionations similar in direction and magnitude to microbial reactions (Johnson et al., 2002; Skulan et al., 2002), the presence of Fe isotope variations is not in itself conclusive evidence of biotic activity. This complicates the ability to use iron isotopes to identify microbiological processing in the rock record (Balci et al., 2006).

Conclusions

“Biological processes fractionate the stable isotopes of C, N, S, and Fe in a characteristic way leading to biosignatures in the geosphere. Such isotope fingerprints have been used as indicators of early life on Earth and Mars. Since abiological processes sometimes may lead to isotope compositions comparable to biological processes, isotope biosignatures have to be applied with care.”

Definition

Radiogenic nuclides (more commonly referred to as “radiogenic isotopes”) are produced by a process of radioactive decay. Radioactive decay means that unstable isotopes (mother nuclides) are spontaneously transferred

into stable isotopes (daughter nuclides) by emission of particles and loss of energy (radioactive radiation).

Introduction

The radioactive decay provides an accurate method of measuring the ages of rocks and minerals. This possibility was recognized both by Rutherford (1906) and Boltwood (1907) at the beginning of the twentieth century. However, the measurement and interpretation of variations in the isotopic composition of certain elements in natural materials were not possible until modern mass spectrometers were developed based on the design by Nier (1940). After the World War II, isotope determinations became an important tool in modern geology, geochemistry, and geobiology not only for dating geological processes, but also for investigations of climate change, environmental, and biological parameters. The most frequently used systems are Rb/Sr, Sr/Sr, Sm/Nd, Nd/Nd, U/Pb, and Pb/Pb. In the following, typical examples of the most common radiogenic isotope applications are presented.

Strontium isotopes

There are four stable isotopes of Sr: ^{88}Sr , ^{87}Sr , ^{86}Sr , and ^{84}Sr . All but ^{87}Sr are nonradiogenic (that is, not the products of radioactive decay), whereas ^{87}Sr is produced by radioactive decay of ^{87}Rb (half-life 0.488×10^9 years). The $^{87}\text{Rb} \rightarrow ^{87}\text{Sr}$ radioactive decay pair has therefore produced different $^{87}\text{Sr}/^{86}\text{Sr}$ ratios depending on the age and the amount of Rubidium in the material investigated. For more than half of the century, the Rb/Sr system is one of the most frequently used decay systems for dating geological events.

The isotopic composition of strontium is not only used for dating purposes, but also has turned out to be a universal tool for describing a variety of geological, biological, and environmental processes.

Groundwater and basement brines

Strontium is easily dissolved in water. The advantage of the strontium isotopic system is that the isotopic composition assumed till recently will not be changed by fractionation processes; it means that strontium in circulation depends on the $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of the rocks and minerals that interact with water at or near the surface of the Earth. The Sr isotope composition of groundwater aquifers is constant over years, independent of the amount of rainfall, as demonstrated in a recent study by Klaus et al. (2007). Investigations in the Bangkok Metropolitan Area showed that the $^{87}\text{Sr}/^{86}\text{Sr}$ ratios are useful tools to characterize groundwater flow and related biological and environmental processes.

Strontium isotope variations also play an important role in evaluating the suitability of crystalline rocks for geological disposal of nuclear waste. At the Hard Rock Laboratory at Äspö in southern Sweden, Sr isotope composition of groundwater has been investigated by Peterman and Walin (1999) down to a depth of 850 m from boreholes. Microbial

biofilms found in the deeper part of the tunnel are controlled in their Sr composition by highly saline brines (58 mg/l and $\delta^{87}\text{Sr}$ values as large as +13.9‰). Mixing with Baltic seawater from the surface (1.5 mg/l and $\delta^{87}\text{Sr}$ values of +0.3‰) is negligible; nevertheless, the method is sensitive enough to show the very small input of Baltic seawater even in the deepest parts of the Äspö tunnel.

Sr isotope investigations on high saline brines within the German Continental Deep Drilling Program (KTB) showed that the Sr isotopic compositions of paleofluids and recent fluids in the upper continental crust can be distinguished by means of $^{87}\text{Sr}/^{86}\text{Sr}$ versus $1/\text{Sr}$ mixture curves (Möller et al., 1997). Similar to saline brines, mesophilic and (hyper) thermophilic microorganisms living in shallow or deeper crust showed different Sr isotope compositions. Hence, Sr isotopic compositions may comprise a promising tool for the correlation of deep biosphere systems with depth and temperature regimes.

Strontium in animal and human skeletons

As the ionic radius of Sr (1.13 Å) is similar to that of Ca (0.99 Å), strontium replaces calcium in organic matters and can therefore also be used as a tracer for animal and human mobility. Different geographic (geological) regions yield different Sr isotopic compositions and as natural variations are not changed through the food chain, the strontium composition measured in skeletal elements can be used to identify the region where an animal or a human being lived (Brian and Johnson, 2000). The $^{87}\text{Sr}/^{86}\text{Sr}$ ratios reflect the Sr that was ingested while a specific skeletal element grew. Because different skeletal elements grow and exchange Sr at different stages during the lifetime, Sr isotopic analyses of different skeletal parts can be used to infer changes in geographic location at different stages in the life of an organism. Regarding a human being, this means that the Sr isotopic composition of the enamel in the teeth will reflect the composition as a child, due to the immobile nature of Sr and Ca in teeth, whereas the Sr composition in a bone (e.g., femur) will reflect the average composition over the last 10 years of life, due to continuous processing of Sr and Ca in bone. These conclusions, however, are only valid for skeletons which are of "High Middle Age" or older. In the time of globalization, no relationship between living place and geogenic Sr input in the food chain can be reconstructed anymore.

Strontium in seawater

Biogenic carbonates are fairly resistant to diagenetic alteration. As they are secreted directly from seawater by the organisms, they contain no detrital material, and therefore reflect the isotopic composition of the seawater at the time of deposition. Biogenic carbonates are nearly free of Rb and can therefore not be dated directly. However, the $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of these carbonates can be used to define the evolution of the seawater isotopic composition by known stratigraphic age deduced from fossils.

Fundamental studies on the Sr seawater evolution curve were published between 1970 (Peterman et al., 1970) and 1982 (Burke et al., 1982). The obtained curves were all based on Sr isotope data from Phanerozoic carbonates. The seawater Sr data set was later extended back to the Late Proterozoic (Derry et al., 1989; Asmerom et al., 1991; Kaufman et al., 1993). In the absence of fossils, these studies were carried out on leached whole-rock carbonate samples to avoid contamination by detrital material (Figure 1).

The seawater evolution curve can not only be used as an indirect dating tool for biogenic precipitations but may also be used as a geobiological tool, e.g., for indicating the setting of carbonate precipitations accompanying methane seeps. Investigations on methane-derived carbonates from the northwestern Black Sea showed $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of microcrystalline carbonates of 0.70927 and aragonitic cement of 0.70918. Both ratios are indistinguishable from ambient seawater (0.70917), and therefore indicate a shallow Sr source (Peckmann et al., 2001). The higher ratio of 0.71005 in the background sediments is related to detrital mica.

Paleotemperatures

Corals are primarily known as archives not only for changes in the sea surface temperature, but also for the variability in salinity and productivity. The latter are reflected in the common proxies such as $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$. However, the temperature equations are only valid for shallow-water corals. Further, proxies such as Sr/Ca, Mg/Ca, and U/Ca are dependent on growth parameters which are linked to specific coral species. As mentioned above, up to now it is assumed that geological processes do not cause any fractionation of the Sr isotopes. Recently, new techniques (Fietzke and Eisenhauer, 2006) have shown that this may not always hold true for calcium carbonate precipitation, including inorganic aragonite precipitation. Temperature-controlled precipitation of aragonite shows only minor variations in the Sr isotope fractionation (0.0054‰/°C) in the $\delta^{88}\text{Sr}/^{86}\text{Sr}$ ratios, whereas a natural coral sample (*Pavona clavus*) shows a fractionation nearly ten times higher (0.033‰/°C) in the $\delta^{88}\text{Sr}/^{86}\text{Sr}$ ratios. This means that the strontium isotope system can also be used as a paleothermometer for the identification of different fluid sources involved in calcium carbonate precipitation at low temperatures and to characterize processes of biomineralization. The consequence of these findings is that the seawater evolution curve discussed above also has to be corrected. The high potential of this method for studying climate-dependent variables especially for cold-water corals is demonstrated in a recent paper by Rüggeberg et al. (2008).

Neodymium isotopes

There are seven stable isotopes of Nd: ^{150}Nd , ^{148}Nd , ^{146}Nd , ^{145}Nd , ^{144}Nd , ^{143}Nd , and ^{142}Nd . All but ^{142}Nd and ^{143}Nd are nonradiogenic (that is, not the products of

Isotopes, Radiogenic, Figure 1 Time-dependent variation of the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of seawater. T = Tertiary, K = Cretaceous, J = Jurassic, TR = Triassic, P = Permian, C = Carboniferous, D = Devonian, S = Silurian, O = Ordovician, ε = Cambrian, V = Vendian, Stu = Sturtian. (Data compiled after McArthur et al., 2001 and Kaufmann et al., 1993.)

radioactive decay). ^{143}Nd is produced by radioactive decay of ^{147}Sm (half-life 10.6×10^{10} years). The $^{147}\text{Sm} \rightarrow ^{143}\text{Nd}$ radioactive decay pair has therefore produced different $^{143}\text{Nd}/^{144}\text{Nd}$ ratios in the investigated materials, depending on the age and the amount of Sm. Due to the short half-life (1.0×10^8 years) of $^{146}\text{Sm} \rightarrow ^{142}\text{Nd}$, this system so far has played no significant role in interpreting geological processes.

Neodymium is, like strontium, released by selective chemical weathering of polycrystalline rocks, and therefore dissolved Nd does not have the same isotopic composition as in the weathered rock. However, particulate matter transported into the sea is a characteristic product of eroded rocks in a given source area on the continent. Bock et al. (2005) showed that young sediments (4300 and 1000 year BP) in the Baltic Sea reflect a substantial change of Nd isotopic composition. This can be related either to changing inputs from the source areas or as different inflow of North Sea water. Variations of both, erosive continental input and North Sea inflow indicate a direct response of the Nd isotope signal in the Baltic Sea to climate change. The authors show that the Nd signal can be related to the cyclic shifts in the atmospheric circulation as well as demographic changes affecting agricultural activities. The reduction of farmland would also cause a reduction of soil erosion that changes the amount and composition of river-transported sediments into the Baltic Sea. This example shows that neodymium isotopic composition of sediment cores is a valuable tool for tracing climate changes.

Glacial-interglacial cycles are reflected in both Sr and Nd isotopic compositions (Tütken et al., 2002). The investigation of Arctic marine sediment cores revealed that it is possible to correlate ice rafted sediments with their source rocks, and therefore the glacial distribution as a function of time. The fact that Sr isotope composition is anticorrelated to the Nd isotopic composition makes such combined isotopic studies very sensitive to climate changes, and therefore also contributes to elucidate biological processes.

Lead isotopes

There are four stable isotopes of lead: ^{208}Pb , ^{207}Pb , ^{206}Pb , and ^{204}Pb . Only ^{204}Pb is not a product of radioactive decay, whereas ^{208}Pb , ^{207}Pb , and ^{206}Pb are produced by radioactive decay of ^{232}Th (half-life 14.010×10^9 years), ^{235}U (half-life 0.7038×10^9 years), and ^{238}U (half-life 4.468×10^9 years), respectively.

The so-called “common lead method” is used for dating minerals whose U/Pb and Th/Pb ratios are so low that their isotopic compositions do not change with time. The obtained ages, however, may vary with the evolution models used for the common lead method. One of the models, “the single-stage model” assumes that the primordial lead isotope ratios evolved in different reservoirs with different U/Pb ratios. This model is named the “Holmes–Hautermans Model” (Holmes, 1946; Hautermans, 1946). The measured isotopic compositions of the lead often resulted in ages which were to be obtained in the future

if the single-stage model was applied. Therefore, the “two-stage” Pb evolution model was proposed by Stacey and Kramers (1975). In this model, Pb evolves from primordial isotope ratios between 4.57 Ga and 3.7 Ga in a reservoir with $^{238}\text{U}/^{204}\text{Pb}$ of 7.192. At 3.7 Ga, the $^{238}\text{U}/^{204}\text{Pb}$ ratio of the reservoir changed by chemical differentiation to 9.735. Thereafter, lead evolution continued without change until present. A line connecting measured isotope ratios ($^{207}\text{Pb}/^{204}\text{Pb}$ vs. $^{206}\text{Pb}/^{204}\text{Pb}$) and the corresponding ratios at 3.7 Ga will intersect with the evolution line; these lines are called isochrones. The slope of these isochrones are related to the time elapsed since a lead sample was extracted from the reservoir, and therefore the age since separation can be calculated. Even if this model gives more geological relevant ages, it is still insufficient for geological dating. Nonetheless, lead isotopes may reveal excellent tracers for environmental investigations and, as lead is a toxic element, for characterizing biological processes. Lead isotope compositions do not change during industrial and environmental processes, and therefore reflect the lead source, thus allowing to distinguish between natural and anthropogenic origins (e.g., Cicchella et al., 2008). The anthropogenic lead has until recently mainly been contributed by leaded gasoline, with additional inputs caused by the combustion of coal. The lead isotopic signature of coal is more radiogenic, as coal is found in sedimentary rocks. Lead from basement rocks, which are the sources of ore deposits, show a different (lower) isotopic signature. Isotope analyses of, e.g., snow and surface waters can therefore contribute to unravel the sources and dynamics of lead in the oceans and the atmosphere and contribute to the database concerning climate change (Hamelin et al., 1997).

Exposure to lead as well as other heavy metals in the environment is a matter of public health concern. The lead isotopes play an important role in the development of biomarkers. Lead transfer across the placental barrier and injections of marked lead (^{206}Pb and ^{204}Pb , respectively) result in deposition in the enamel. Analyses of the enamels can be used to observe biological removal and assimilation of prenatal and postnatal tracers, respectively. This technique can be used to demonstrate the toxicokinetics of incorporating lead into fetal and neonatal steady-state system processes (Rinderknecht et al., 2005). The accumulation of heavy metals in aquatic organisms through the food chain may lead to serious health problems. Investigations of lead isotopes showed that the bioaccumulation of Pb in fish is due to a wide variety of food sources and/or exposure pathways, particularly anthropogenic inputs (Ip et al., 2005). These are only a few examples of the usefulness of lead isotopes in modern environmental research which becomes more important with increasing pollution.

Conclusions

Summarizing the applicability of selected radiogenic isotope systems, it can be concluded that a very wide field of applications can be covered, not only traditional dating

of geological events but also numerous applications in geological, (geo)biological, environmental, archeological, and forensic processes can be answered by means of radiogenic isotope investigations (further application references can be found in Hansen, 2005).

ISOTOPES AND GEOBIOLOGY

Jochen Hoefs
University of Göttingen, Göttingen, Germany

Definition

It has long been recognized (e.g., Thode et al. (1949), Craig (1953) and Wellman et al. (1968)) that biological processes significantly fractionate the isotopes of C, N, and S, leading to characteristic *biosignatures* in sedimentary rocks that will be more or less preserved in the geological record. In the following, a brief overview is given of the major isotope fractionation processes in the biosphere and the geosphere. Special attention will be paid to secondary bacterial activity after deposition of the organic matter. Questions of general interest are isotopic indicators of early life on Earth and on Mars. A note of caution, however, is given whether abiogenic processes may lead to isotope compositions similar to that of biological activity.

Carbon isotope fractionation during photosynthesis

Early reviews by O’Leary (1981) and Farquhar et al. (1989) have provided the biochemical background of carbon isotope fractionations during photosynthesis, with more recent accounts by Hayes (2001) and Freeman (2001). The main isotope-discriminating steps during biological carbon fixation are (1) the uptake and intracellular diffusion of CO_2 and (2) the biosynthesis of cellular components. Such a two-step model was first proposed by Park and Epstein (1960):

From this simplified scheme, it follows that the diffusional process is reversible, whereas the enzymatic carbon fixation is irreversible. The two-step model of carbon fixation clearly suggests that isotope fractionation is dependent on the partial pressure of CO_2 , i.e., $p\text{CO}_2$ of the system. With an unlimited amount of CO_2 available to a plant, the enzymatic fractionation will determine the isotopic difference between the inorganic carbon source and the final bioproduct. Under these conditions, ^{13}C fractionations may vary from -17 to -40‰ (O’Leary, 1981). When the concentration of CO_2 is the limiting factor, the diffusion of CO_2 into the plant is the slow step in the reaction and carbon isotope fractionation of the plant decreases.

CARBONATE ENVIRONMENTS

Eberhard Gischler

J.W. Goethe-Universität, Frankfurt am Main, Germany

Definition

Carbonate environments occur both in the terrestrial and marine realms as well as in transitional zones between the land and the sea. The variety of environments spans from high-elevation continental lakes to the deep sea, from the equator to latitudes of about 60°, and they include dry and wet climate realms. The majority of carbonates are produced in the sea, currently in more or less similar proportions in neritic and pelagic settings. Carbonate production is to a large part a consequence of biological activity, either directly as in shell and skeleton formation or indirectly as a result of metabolic reactions, which trigger precipitation. The highest rates of carbonate production per unit time and space are probably reached in tropical coral reefs where several kilograms of calcium carbonate form on 1 m² during 1 year's time.

Introduction

Modern carbonate sediments are largely a product of biologic activity, either enzymatically controlled like in calcium carbonate (CaCO₃) shell and skeleton formation of aquatic organisms or indirectly by the metabolic activity

ISOTOPES, RADIOGENIC

Bent T. Hansen
 University of Göttingen, Göttingen, Germany

Definition

Radiogenic nuclides (more commonly referred to as “radiogenic isotopes”) are produced by a process of radioactive decay. Radioactive decay means that unstable isotopes (mother nuclides) are spontaneously transferred

into stable isotopes (daughter nuclides) by emission of particles and loss of energy (radioactive radiation).

Introduction

The radioactive decay provides an accurate method of measuring the ages of rocks and minerals. This possibility was recognized both by Rutherford (1906) and Boltwood (1907) at the beginning of the twentieth century. However, the measurement and interpretation of variations in the isotopic composition of certain elements in natural materials were not possible until modern mass spectrometers were developed based on the design by Nier (1940). After the World War II, isotope determinations became an important tool in modern geology, geochemistry, and geobiology not only for dating geological processes, but also for investigations of climate change, environmental, and biological parameters. The most frequently used systems are Rb/Sr, Sr/Sr, Sm/Nd, Nd/Nd, U/Pb, and Pb/Pb. In the following, typical examples of the most common radiogenic isotope applications are presented.

Strontium isotopes

There are four stable isotopes of Sr: ^{88}Sr , ^{87}Sr , ^{86}Sr , and ^{84}Sr . All but ^{87}Sr are nonradiogenic (that is, not the products of radioactive decay), whereas ^{87}Sr is produced by radioactive decay of ^{87}Rb (half-life 0.488×10^9 years). The $^{87}\text{Rb} \rightarrow ^{87}\text{Sr}$ radioactive decay pair has therefore produced different $^{87}\text{Sr}/^{86}\text{Sr}$ ratios depending on the age and the amount of Rubidium in the material investigated. For more than half of the century, the Rb/Sr system is one of the most frequently used decay systems for dating geological events.

The isotopic composition of strontium is not only used for dating purposes, but also has turned out to be a universal tool for describing a variety of geological, biological, and environmental processes.

Groundwater and basement brines

Strontium is easily dissolved in water. The advantage of the strontium isotopic system is that the isotopic composition assumed till recently will not be changed by fractionation processes; it means that strontium in circulation depends on the $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of the rocks and minerals that interact with water at or near the surface of the Earth. The Sr isotope composition of groundwater aquifers is constant over years, independent of the amount of rainfall, as demonstrated in a recent study by Klaus et al. (2007). Investigations in the Bangkok Metropolitan Area showed that the $^{87}\text{Sr}/^{86}\text{Sr}$ ratios are useful tools to characterize groundwater flow and related biological and environmental processes.

Strontium isotope variations also play an important role in evaluating the suitability of crystalline rocks for geological disposal of nuclear waste. At the Hard Rock Laboratory at Äspö in southern Sweden, Sr isotope composition of groundwater has been investigated by Peterman and Walin (1999) down to a depth of 850 m from boreholes. Microbial

biofilms found in the deeper part of the tunnel are controlled in their Sr composition by highly saline brines (58 mg/l and $\delta^{87}\text{Sr}$ values as large as +13.9‰). Mixing with Baltic seawater from the surface (1.5 mg/l and $\delta^{87}\text{Sr}$ values of +0.3‰) is negligible; nevertheless, the method is sensitive enough to show the very small input of Baltic seawater even in the deepest parts of the Äspö tunnel.

Sr isotope investigations on high saline brines within the German Continental Deep Drilling Program (KTB) showed that the Sr isotopic compositions of paleofluids and recent fluids in the upper continental crust can be distinguished by means of $^{87}\text{Sr}/^{86}\text{Sr}$ versus $1/\text{Sr}$ mixture curves (Möller et al., 1997). Similar to saline brines, mesophilic and (hyper) thermophilic microorganisms living in shallow or deeper crust showed different Sr isotope compositions. Hence, Sr isotopic compositions may comprise a promising tool for the correlation of deep biosphere systems with depth and temperature regimes.

Strontium in animal and human skeletons

As the ionic radius of Sr (1.13 Å) is similar to that of Ca (0.99 Å), strontium replaces calcium in organic matters and can therefore also be used as a tracer for animal and human mobility. Different geographic (geological) regions yield different Sr isotopic compositions and as natural variations are not changed through the food chain, the strontium composition measured in skeletal elements can be used to identify the region where an animal or a human being lived (Brian and Johnson, 2000). The $^{87}\text{Sr}/^{86}\text{Sr}$ ratios reflect the Sr that was ingested while a specific skeletal element grew. Because different skeletal elements grow and exchange Sr at different stages during the lifetime, Sr isotopic analyses of different skeletal parts can be used to infer changes in geographic location at different stages in the life of an organism. Regarding a human being, this means that the Sr isotopic composition of the enamel in the teeth will reflect the composition as a child, due to the immobile nature of Sr and Ca in teeth, whereas the Sr composition in a bone (e.g., femur) will reflect the average composition over the last 10 years of life, due to continuous processing of Sr and Ca in bone. These conclusions, however, are only valid for skeletons which are of "High Middle Age" or older. In the time of globalization, no relationship between living place and geogenic Sr input in the food chain can be reconstructed anymore.

Strontium in seawater

Biogenic carbonates are fairly resistant to diagenetic alteration. As they are secreted directly from seawater by the organisms, they contain no detrital material, and therefore reflect the isotopic composition of the seawater at the time of deposition. Biogenic carbonates are nearly free of Rb and can therefore not be dated directly. However, the $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of these carbonates can be used to define the evolution of the seawater isotopic composition by known stratigraphic age deduced from fossils.

Fundamental studies on the Sr seawater evolution curve were published between 1970 (Peterman et al., 1970) and 1982 (Burke et al., 1982). The obtained curves were all based on Sr isotope data from Phanerozoic carbonates. The seawater Sr data set was later extended back to the Late Proterozoic (Derry et al., 1989; Asmerom et al., 1991; Kaufman et al., 1993). In the absence of fossils, these studies were carried out on leached whole-rock carbonate samples to avoid contamination by detrital material (Figure 1).

The seawater evolution curve can not only be used as an indirect dating tool for biogenic precipitations but may also be used as a geobiological tool, e.g., for indicating the setting of carbonate precipitations accompanying methane seeps. Investigations on methane-derived carbonates from the northwestern Black Sea showed $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of microcrystalline carbonates of 0.70927 and aragonitic cement of 0.70918. Both ratios are indistinguishable from ambient seawater (0.70917), and therefore indicate a shallow Sr source (Peckmann et al., 2001). The higher ratio of 0.71005 in the background sediments is related to detrital mica.

Paleotemperatures

Corals are primarily known as archives not only for changes in the sea surface temperature, but also for the variability in salinity and productivity. The latter are reflected in the common proxies such as $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$. However, the temperature equations are only valid for shallow-water corals. Further, proxies such as Sr/Ca, Mg/Ca, and U/Ca are dependent on growth parameters which are linked to specific coral species. As mentioned above, up to now it is assumed that geological processes do not cause any fractionation of the Sr isotopes. Recently, new techniques (Fietzke and Eisenhauer, 2006) have shown that this may not always hold true for calcium carbonate precipitation, including inorganic aragonite precipitation. Temperature-controlled precipitation of aragonite shows only minor variations in the Sr isotope fractionation (0.0054‰/°C) in the $\delta^{88}\text{Sr}/^{86}\text{Sr}$ ratios, whereas a natural coral sample (*Pavona clavus*) shows a fractionation nearly ten times higher (0.033‰/°C) in the $\delta^{88}\text{Sr}/^{86}\text{Sr}$ ratios. This means that the strontium isotope system can also be used as a paleothermometer for the identification of different fluid sources involved in calcium carbonate precipitation at low temperatures and to characterize processes of biomineralization. The consequence of these findings is that the seawater evolution curve discussed above also has to be corrected. The high potential of this method for studying climate-dependent variables especially for cold-water corals is demonstrated in a recent paper by Rüggeberg et al. (2008).

Neodymium isotopes

There are seven stable isotopes of Nd: ^{150}Nd , ^{148}Nd , ^{146}Nd , ^{145}Nd , ^{144}Nd , ^{143}Nd , and ^{142}Nd . All but ^{142}Nd and ^{143}Nd are nonradiogenic (that is, not the products of

Isotopes, Radiogenic, Figure 1 Time-dependent variation of the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of seawater. T = Tertiary, K = Cretaceous, J = Jurassic, TR = Triassic, P = Permian, C = Carboniferous, D = Devonian, S = Silurian, O = Ordovician, ε = Cambrian, V = Vendian, Stu = Sturtian. (Data compiled after McArthur et al., 2001 and Kaufmann et al., 1993.)

radioactive decay). ^{143}Nd is produced by radioactive decay of ^{147}Sm (half-life 10.6×10^{10} years). The $^{147}\text{Sm} \rightarrow ^{143}\text{Nd}$ radioactive decay pair has therefore produced different $^{143}\text{Nd}/^{144}\text{Nd}$ ratios in the investigated materials, depending on the age and the amount of Sm. Due to the short half-life (1.0×10^8 years) of $^{146}\text{Sm} \rightarrow ^{142}\text{Nd}$, this system so far has played no significant role in interpreting geological processes.

Neodymium is, like strontium, released by selective chemical weathering of polycrystalline rocks, and therefore dissolved Nd does not have the same isotopic composition as in the weathered rock. However, particulate matter transported into the sea is a characteristic product of eroded rocks in a given source area on the continent. Bock et al. (2005) showed that young sediments (4300 and 1000 year BP) in the Baltic Sea reflect a substantial change of Nd isotopic composition. This can be related either to changing inputs from the source areas or as different inflow of North Sea water. Variations of both, erosive continental input and North Sea inflow indicate a direct response of the Nd isotope signal in the Baltic Sea to climate change. The authors show that the Nd signal can be related to the cyclic shifts in the atmospheric circulation as well as demographic changes affecting agricultural activities. The reduction of farmland would also cause a reduction of soil erosion that changes the amount and composition of river-transported sediments into the Baltic Sea. This example shows that neodymium isotopic composition of sediment cores is a valuable tool for tracing climate changes.

Glacial-interglacial cycles are reflected in both Sr and Nd isotopic compositions (Tütken et al., 2002). The investigation of Arctic marine sediment cores revealed that it is possible to correlate ice rafted sediments with their source rocks, and therefore the glacial distribution as a function of time. The fact that Sr isotope composition is anticorrelated to the Nd isotopic composition makes such combined isotopic studies very sensitive to climate changes, and therefore also contributes to elucidate biological processes.

Lead isotopes

There are four stable isotopes of lead: ^{208}Pb , ^{207}Pb , ^{206}Pb , and ^{204}Pb . Only ^{204}Pb is not a product of radioactive decay, whereas ^{208}Pb , ^{207}Pb , and ^{206}Pb are produced by radioactive decay of ^{232}Th (half-life 14.010×10^9 years), ^{235}U (half-life 0.7038×10^9 years), and ^{238}U (half-life 4.468×10^9 years), respectively.

The so-called “common lead method” is used for dating minerals whose U/Pb and Th/Pb ratios are so low that their isotopic compositions do not change with time. The obtained ages, however, may vary with the evolution models used for the common lead method. One of the models, “the single-stage model” assumes that the primordial lead isotope ratios evolved in different reservoirs with different U/Pb ratios. This model is named the “Holmes–Hautermans Model” (Holmes, 1946; Hautermans, 1946). The measured isotopic compositions of the lead often resulted in ages which were to be obtained in the future

if the single-stage model was applied. Therefore, the “two-stage” Pb evolution model was proposed by Stacey and Kramers (1975). In this model, Pb evolves from primordial isotope ratios between 4.57 Ga and 3.7 Ga in a reservoir with $^{238}\text{U}/^{204}\text{Pb}$ of 7.192. At 3.7 Ga, the $^{238}\text{U}/^{204}\text{Pb}$ ratio of the reservoir changed by chemical differentiation to 9.735. Thereafter, lead evolution continued without change until present. A line connecting measured isotope ratios ($^{207}\text{Pb}/^{204}\text{Pb}$ vs. $^{206}\text{Pb}/^{204}\text{Pb}$) and the corresponding ratios at 3.7 Ga will intersect with the evolution line; these lines are called isochrones. The slope of these isochrones are related to the time elapsed since a lead sample was extracted from the reservoir, and therefore the age since separation can be calculated. Even if this model gives more geological relevant ages, it is still insufficient for geological dating. Nonetheless, lead isotopes may reveal excellent tracers for environmental investigations and, as lead is a toxic element, for characterizing biological processes. Lead isotope compositions do not change during industrial and environmental processes, and therefore reflect the lead source, thus allowing to distinguish between natural and anthropogenic origins (e.g., Cicchella et al., 2008). The anthropogenic lead has until recently mainly been contributed by leaded gasoline, with additional inputs caused by the combustion of coal. The lead isotopic signature of coal is more radiogenic, as coal is found in sedimentary rocks. Lead from basement rocks, which are the sources of ore deposits, show a different (lower) isotopic signature. Isotope analyses of, e.g., snow and surface waters can therefore contribute to unravel the sources and dynamics of lead in the oceans and the atmosphere and contribute to the database concerning climate change (Hamelin et al., 1997).

Exposure to lead as well as other heavy metals in the environment is a matter of public health concern. The lead isotopes play an important role in the development of biomarkers. Lead transfer across the placental barrier and injections of marked lead (^{206}Pb and ^{204}Pb , respectively) result in deposition in the enamel. Analyses of the enamels can be used to observe biological removal and assimilation of prenatal and postnatal tracers, respectively. This technique can be used to demonstrate the toxicokinetics of incorporating lead into fetal and neonatal steady-state system processes (Rinderknecht et al., 2005). The accumulation of heavy metals in aquatic organisms through the food chain may lead to serious health problems. Investigations of lead isotopes showed that the bioaccumulation of Pb in fish is due to a wide variety of food sources and/or exposure pathways, particularly anthropogenic inputs (Ip et al., 2005). These are only a few examples of the usefulness of lead isotopes in modern environmental research which becomes more important with increasing pollution.

Conclusions

Summarizing the applicability of selected radiogenic isotope systems, it can be concluded that a very wide field of applications can be covered, not only traditional dating

of geological events but also numerous applications in geological, (geo)biological, environmental, archeological, and forensic processes can be answered by means of radiogenic isotope investigations (further application references can be found in Hansen, 2005).

KARST ECOSYSTEMS

Annette S. Engel
Louisiana State University, Baton Rouge, LA, USA

Definition

Karst. A landscape in and on the Earth's surface produced by the natural processes of solution and leaching of soluble rocks, generally carbonate rocks (e.g., limestone), in which the ensuing topography is mainly characterized by sinkholes, sinking streams, underground drainage networks, and caves.

Introduction

Karst landscapes comprise ~15–20% of the Earth's ice-free land surface. Because karst forms in soluble rocks, the global occurrence coincides roughly with the distribution of carbonate sedimentary rocks (e.g., Ford and Williams, 2007) (see Chapters *Carbonates* and *Carbonate Environments*). Karst landscapes link the Earth's surface to the subsurface, being characterized by features such as sinking streams, sinkholes, caves, and extensive underground water flow systems. Caves, which can extend up to 100 m into the subsurface, are solutionally- or collapse-enlarged discontinuous openings in rock. Surface karst features neither have to be extensively developed, nor present, for subsurface karst development and aquifer processes to be operative. Approximately, 25% of the global population depends upon the health of karst terrains and karst aquifers for its water supply (Ford and Williams, 2007).

Air, water, and rock within karst landscapes offer reactive interfaces for microbial activity. Considering the extent to which carbonate rocks comprise the rock record, and the depths to which subsurface carbonates can be karstified, the microbial biomass within karst settings

and at karst interfaces is potentially tremendous. Hence, microbial diversity and microbial processes are central to all of the karst-related sciences. Moreover, as some karst landscapes have remained relatively unchanged for thousands, if not millions, of years (e.g., Gale, 1992), the longevity of the karst habitat makes karst a potentially long-term reservoir for microbial communities and subsurface ecosystems (see Chapter *Deep Biosphere of Continental Rocks*). The goals of this review are two-fold: (1) to summarize the geobiology of karst ecosystems by describing the range of karst habitats that are important to maintain biological (and microbiological) diversity, and (2) to examine the range of geochemical, mineralogic, and ecological processes that are influenced by microbes in karst.

Types of caves and karst

Karst development, and subsequently cave formation (speleogenesis), is primarily due to rock dissolution, mechanical weathering, volcanic activity, or the melting of glacial ice (Figure 1). Karst can be classified in a number of ways, including from determining the solid that a feature has developed within (e.g., limestone, dolomite, gypsum, basalt, granite), the proximity to the groundwater table (e.g., above, at, or below it), the origin of the feature, and the morphology of the feature (e.g., cave passage shape, cave length, passage arrangement, passage levels). As Figure 1 demonstrates, there are a number of karst, pseudokarst, and cave types. One of the dominant karst-forming processes is the dissolution of soluble rock by the action of water, forming solution, or dissolution caves (White and Culver, 2000; Palmer, 2007); consequently, most caves are dissolutional in origin. Erosion caves also develop by moving water, but from mechanical weathering (e.g., scouring or wave active) rather than from dissolution. Dissolution caves can transit into erosion caves through time. Sea caves form

Karst Ecosystems, Figure 1 Common types of karst and processes responsible for forming a variety of caves. The processes of dissolution (epigenic or hypogenic) and weathering can also modify rejuvenated paleokarst. (Modified from White and Culver, 2000.)

as erosional caves along sea coasts in carbonate or basaltic rock, but anchialine caves typically form from dissolution along the sea coasts (see Chapter *Caves, Submarine*). Volcanic caves, or lava tubes, are starkly different than dissolution caves, resulting from a crust that formed at the surface of flowing lava while the remaining fluid (e.g., lava) continued to flow beneath the crust. The reader should review Palmer (2007) and Ford and Williams (2007) for more information about cave and karst types and speleogenetic processes. Some karst features are rare (e.g., White and Culver, 2000; Palmer, 2007), and few geobiological studies have been conducted in those settings. Therefore, this chapter focuses on dissolution caves, but briefly describes some research from lava tubes.

For dissolution caves, the proximity to the groundwater table (i.e., whether within the phreatic or vadose zone) and hydrologic conditions (i.e., confined or unconfined aquifer) are critical to the development of the karst system. When formed from dissolution at or above the water table, perhaps due to underground stream flow and/or the gravity-driven movement of meteoric waters, these

features are termed epigenic. Mammoth Cave in Kentucky (USA), at over 580 km of mapped cave passages, is the longest cave currently known and epitomizes epigenic systems worldwide (Palmer, 2007).

Epigenic development proceeds due to carbonic acid (H_2CO_3^0) promoted dissolution of carbonate rocks, such as those consisting of calcite (CaCO_3), whereby $\text{H}_2\text{O} + \text{CO}_2 \rightarrow \text{H}_2\text{CO}_3^0$, and so

These reactions are generally considered fast, and are usually modeled as being at equilibrium (e.g., White, 1997). Through time, epigenic karst development is controlled by the hydrological connectivity to the surface, as well as the complexity of flow path and storativity in the subsurface, rate of water movement, antecedent geochemical conditions, as well as the composition, function, and activities of microbes within the groundwater system. The location and arrangement of epigenic cave passages relative to overall landscape and surface drainage basin evolution

reflect local to regional base level, hydrological characteristics, and climate. Climate change can directly affect karst development because carbonate dissolution is directly related to CO_2 solubility, which is proportional to partial pressure (P_{CO_2}) and inversely proportional to temperature.

In contrast, hypogenic caves and karst form at or below the water table due to the action of rising fluids (water or gases), with little or no relationship to surface karst features or processes (Klimchouk, 2007). Various types of hypogenic caves can develop (Figure 1), with one of the most dramatic being due to the activity of sulfuric acid. At least 10% of carbonate caves worldwide have been attributed to this process (Palmer, 1991; Engel, 2007), including some ancient caves such as Carlsbad Cavern, New Mexico (USA) (Hill, 1996; Polyak et al., 1998). Egemeier (1981) was one of the first to examine in detail the sulfuric acid process. By observing hydrogen sulfide (H_2S)-bearing thermal springs in Lower Kane Cave in Wyoming (USA), extensive gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) deposits, and gypsum-replaced carbonate rock walls, he hypothesized that volatilization of H_2S from the sulfidic groundwater to the cave atmosphere, and H_2S autooxidation to sulfuric acid on the moist cave walls, caused the carbonate rock to be replaced with gypsum through the dissolution-replacement mechanism,

Because most natural low-temperature waters are undersaturated with respect to gypsum, the net result is mass removal and an increase in void volume. Nearly all of the subsequent studies regarding sulfuric acid speleogenesis assumed that H_2S was oxidized and consequently the sulfuric acid was produced by strictly abiotic processes. However, sulfur-oxidizing bacteria (see Chapter *Thiotrophic Bacteria*), which can generate sulfuric acid as a by-product of their metabolism, play an important role in carbonate dissolution (Engel et al., 2004b). Based on work from several sulfidic caves and the Edwards Aquifer in Central Texas (USA), it has been demonstrated that microbes focus acidity at the site of colonization and locally dissolve carbonates to a greater extent than the bulk karst fluids are capable of, because they are usually supersaturated with respect to carbonate phases (Engel, 2007).

For the most part, however, recognizing whether a cave has formed from hypogenic processes or not is still a matter of debate (Klimchouk, 2007). Hypogenic caves are considered rare, even if hypogenic processes are perhaps important to nascent karst development (e.g., Palmer, 1991; Palmer, 1995; Klimchouk, 2007). The debate is perpetuated because most caves and karst terrains have polyphasic speleogenetic histories; this means that inception may have been due to hypogenic processes, but that tectonic activities or climate change may force a shift to epigenic development due to evolving base-level conditions or fluid geochemistry (Figure 1). Hypogenic development is usually not influenced by

surface hydrologic processes, as passages do not reflect contemporaneous surface drainage basin patterns. But, in some instances, polyphasic development, and epigenic processes specifically (e.g., sediment deposition due to surface-subsurface drainage, speleothem formation, etc.), may completely overprint evidence pointing to past hypogenic development. From a geobiological perspective, the role of microbes in both epigenic and hypogenic processes also confounds interpretation. Moreover, changes from one development type to another may impact how microbes come to colonize and become distributed within the subsurface. Microbial populations could potentially become isolated from each other during habitat modification. Similarly, changes in geochemical regime will impact the types of organisms that can grow, or tolerate, the new conditions, such as being thrust from oxygenated conditions to sulfidic and reducing conditions, or from neutral pH to acidic conditions (see Chapter *Extreme Environments*).

The cave habitat

The cave habitat is divided into three major zones based on light intensity: entrance, twilight, and dark zone (Figure 2). Each habitat zone has a certain set of physicochemical and nutrient conditions that control the types of organisms present in that zone. Cave and karst habitats have nearly constant temperatures and stable geochemical conditions, although some sections of a cave may change rapidly, such as in a stream due to seasonal or periodic flooding, or even within the entrance zone from daily changes in light level. But, it is the subtle physicochemical variability, availability, and speciation of redox-sensitive elements from one site to another within a cave, and the types and loading of carbon and other nutrients that can influence the diversity and metabolism of (micro) organisms that will colonize karst. Within the different zones, aquatic and terrestrial (or subaerial) habitat conditions are distinctive, and the stresses exerted on organisms will be specific. There is potentially less noticeable stress for aquatic organisms compared to the desiccation or nutritional stresses for organism living on dry cave-wall surfaces (e.g., Barton et al., 2007), although it was the juxtaposition of perceived stable physicochemical conditions to possibly extreme environmental circumstances that originally attracted biologists to study cave and karst organisms.

Consequently, speleologists who first began investigating the life of caves were predominately interested in the strange and exotic animals that they found. Troglobites are cave-adapted terrestrial animals, and stygobites are groundwater-adapted animals. Cave-adapted animals have evolved unique characteristics suitable for the subsurface habitat. Some of the organisms that live in caves are able to move freely in and out of a cave (e.g., troglonenes, such as bats and cave crickets), whereas other organisms (e.g., microbes) are more likely to be dependent on transport or translocation to move them into or

Karst Ecosystems, Figure 2 Cave habitat zones, using an epigenic, dissolution cave as the example. Open circles represent sites where microbial processes can occur, such as on rock surfaces and at interfaces, including within sediment or water. A schematic of microbial carbon cycling is shown from the dark zone, within a cave stream, where the by-products of microbial carbon degradation and processing would be consumed by various higher trophic level organisms. Specific chemolithoautotrophic processes are not shown.

throughout a cave. Unlike the obvious transport mechanism from surface-derived drip waters, however, the extent to which air currents and groundwaters bring microbes into the cave environment is unknown. But, because microbes can also colonize virtually every surface and interface in all zones from a cave system (Figure 2), it is clear that understanding their diversity and their activities are central issues to all of the karst-related sciences (e.g., Rusterholtz and Mallory, 1994; Mahler et al., 2000; Jones, 2001; Northup and Lavoie, 2001; Simon et al., 2003; Cacchio et al., 2004; Farnleitner et al., 2005; Barton, 2006; Goldscheider et al., 2006; Ikner et al., 2007).

As photosynthesis is not possible in the dark zone, most cave and karst ecosystems are assumed to be dependent on allochthonous material brought into the system by wind, speleothem drip waters, stream drainage, as guano, and by the processing of the organic matter by microorganisms. Karst ecosystem energy flow has been poorly investigated (e.g., Simon, 2000; Simon et al., 2003), summarized in Figure 3, where cave ecosystem energy flow is compared to open surface stream energy flow. The most common type of allochthonous material is as dissolved and particulate (coarse and fine) organic matter (DOM, CPOM, and FPOM) (Figure 3), although it is possible that a wide size range can be found in caves, depending on the complexity of passages (e.g., when cave entrances and passages are sufficiently large, catastrophic flooding can bring tree trunks and automobiles deep inside caves). In some shallow settings, including in lava tubes, plant roots (rootsicles) may penetrate cave passages or aquifers and rich biota have been described from these settings (e.g., Howarth, 1973; Jasinska et al., 1996).

Some researchers have suggested that depauperate allochthonous food sources have influenced the evolution

of organisms within the subsurface and could be one reason for the diversity of organisms in epigenic caves. In general, troglobitic and stygobitic diversity is generally low compared to the diversity of surface organisms; in fairness, however, other reasons could include reduced habitat diversity (e.g., Sket, 1999), as well as fragmentation of the habitat and restricted opportunities for dispersal (Culver, 1970; Gibert, 1986; Culver and Sket, 2000). Similarly, trophic structure diversity may also be impacted by the reduced energy within the ecosystem, demonstrated by the elimination of shredders from food webs with increasing isolation from the surface and allochthonous energy input (Figure 3). Unfortunately, very little research has been conducted that addresses the mechanisms that modulate trophic structure in karst ecosystems, or that characterizes organism behavior to understand trophic functional roles.

Based on the research that has been done from caves and karst, however, the “world is green” view is beginning to change. Microbes are not just translocated soil heterotrophic, chemoorganotrophic, or fecal coliform communities that are food sources for higher trophic level organisms (Figure 3). In the absence of sunlight, groundwater rich in redox-sensitive compounds and reactive mineral surfaces (e.g., methane, hydrogen sulfide, or other reduced substances such as iron or manganese) can be used as energy sources by chemolithoautotrophs (Figure 3) (see Chapter *Chemolithotrophy*). In 1986, it was the discovery of the chemolithoautotrophically based cave ecosystem from Movile Cave in southeastern Romania that started to change our perceptions of what types of microbial activities could occur in the subsurface, as well as what types of ecosystem could be expected from such activities (Sarbu et al., 1996). Movile Cave is an access point to a large sulfidic aquifer and currently,

Karst Ecosystems, Figure 3 Energy and carbon flow in aquatic habitats, including surface streams and caves streams that may or may not be connected to the surface, modified from Simon (2000). CPOM represents coarse particulate organic matter, FPOM is fine particulate organic matter, and DOM represents dissolved organic matter. The role of microbes in these ecosystems is predominately as degraders or allochthonous organic material. However, there is the possibility that microbial primary productivity may augment the cave ecosystems carbon and energy budget. There are some cave and karst cave systems where energy and organic matter are sourced from chemolithoautotrophic primary productivity, whereby the ecosystem is entirely dependent on microbial activities. DIC represents dissolved inorganic carbon.

there have been 33 new cave-adapted taxa identified from 30 terrestrial species (24 endemic troglobites) and 18 aquatic species (nine endemic stygobites). Chemolithoautotrophic primary productivity estimated for Movile Cave was as high as $281 \text{ g C m}^{-2} \text{ year}^{-1}$, being comparable to

rates estimated from other aquatic surface systems (Porter, 1999). Based on the carbon to nitrogen ratios, the microbial mats in these sulfidic caves are also a high-quality food source (Porter, 1999; Engel et al., 2004a), although there have been relatively few studies that explore the

assimilation efficiency of higher trophic level organisms who feed on the mats in the sulfidic caves. The diversity and endemism of stygobites and troglobites from sulfidic ecosystems, compared to epigenic cave ecosystems dependent on allochthonous energy, may be related to the rates of autotrophic primary productivity and the quality and quantity of the food source (Engel, 2007).

Most of the research describing chemolithoautotrophy, in caves and karst has been from hypogenic systems and anchialine caves (e.g., Sarbu et al., 1996; Humphreys, 1999a; Opsahl and Chanton, 2006; Engel, 2007). For example, the sulfur-based ecosystems from the Frasassi Caves (Italy) (e.g., Vlasceanu et al., 2000; Macalady et al., 2006, p 59), the Cueva de Villa Luz (Mexico) (Hose et al., 2000), and some stratified sinkholes around the world (e.g., Stoessell et al., 1993; Pohlman et al., 1997), are also based in chemolithoautotrophy. Similarly, microbes have been implicated in sustaining the ecosystems within the Edwards Aquifer in Central Texas (USA) (e.g., Longley, 1981) and the Cape Range or Pilbara aquifers in Australia (e.g., Humphreys, 1999b; Eberhard et al., 2005), although the role of autotrophy is currently not known. The recent discovery of the Ayalon Cave ecosystem in Israel, with possibly a new chemosynthetically based ecosystem and eight invertebrates new to science, is testimony that substantial and unknown subterranean diversity still exists (Por, 2007). Evidence that microbial autotrophy from methane cycling serves as a base for the Upper Floridan Aquifer (USA) ecosystem trophic structure has been suggested from isotope systematics (Opsahl and Chanton, 2006). Recognition of methane-based cave and karst ecosystems can transform what we thought we knew of ecosystem function and the geobiology of karst. Lastly, some work on microbial autotrophy has also been done from epigenic systems, finding that sediments and biofilms on cave walls and in streams also contain chemolithoautotrophic microbial communities (e.g., Simon et al., 2003; Farnleitner et al., 2005) and that karst waters can have high microbial cell abundances and DOM is associated with autochthonous microbial activities rather than plant- or soil-derived humic substance (e.g., Goldscheider et al., 2006). This research direction will impact our understanding of contaminant transport in karst (e.g., Mahler et al., 2000; van Beynen and Townsend, 2005).

Geobiology and microbial activities

Despite knowing little about microeukaryotes and viruses from karst, we do know that all three domains of life and viruses occur in caves and karst. Figure 4 summarizes the variety of cave habitats with microbial communities, and associated microbial processes that have been studied to date. Details regarding the geomicrobiology of caves and karst have been reviewed in a variety of venues (e.g., Jones, 2001; Northup and Lavoie, 2001; Barton, 2006; Barton and Northup, 2007), so the reader should refer to these papers for more information. Here,

discussion begins with lava tubes because comparatively little is known about the microbial diversity, activities, and ecosystem parameters. Some of the most recent research using molecular techniques that have elucidated microbial activities and diversity of hypogenic and epigenic caves and karst, in the context of key processes, is also described (see Chapters *Geomicrobiology*, *Molecular Aspects*, *Molecular Geomicrobiology*, and *Phylogenetics*). The chapter is concluded with future perspectives on cave and karst geobiological studies.

Lava tubes and basaltic caves

There are few studies of microbes from basaltic lava tube or sea caves. Several investigations focus on humid lava tubes, rather than dry basaltic systems (e.g., Northup and Welbourn, 1997, in press), and on rootsicles from lava tubes that support complex fungi and arthropod diversity (e.g., Howarth, 1973, 1981) (Figure 4). From rRNA gene surveys and culture-based growth studies, humid lava tubes contain a variety of slime deposits, consisting of actinomycetes and members within the *Chloroflexi*, *Verrucomicrobia*, and *Proteobacteria* (Ashmole et al., 1992; Northup and Welbourn, 1997). Somewhat related has been the geomicrobiological and mineralogical work on microbial biofilms in the photic zone of basaltic sea caves in Hawaii (USA) (Leveille et al., 2000).

Hypogenic caves

Early research was based on microscopy and culturing (e.g., Hubbard et al., 1986; Olson and Thompson, 1988; Stoessell et al., 1993; Brigmon et al., 1994), but more recently the known microbial diversity from these systems has been expanded by molecular genetics, and specifically from 16S rRNA gene sequence surveys. The biodiversity and geomicrobiology of active sulfidic caves have been more extensively studied than from other types of hypogenic karst, and the reader should refer to these publications for specifics (e.g., Brigmon et al., 1994; Angert et al., 1998; Hose et al., 2000; Barton, 2006; Macalady et al., 2006; Barton and Northup, 2007; Engel, 2007). Microbes in hypogenic systems occur in microbial mats in streams and pools, sediments, elemental sulfur and other mineral deposits, and as snottites or microbial draperies on cave-wall surfaces (e.g., Hose et al., 2000; Macalady et al., 2007), as well as in corrosion residues (e.g., Northup et al., 2000, 2003) (Figure 4). The role of microbes in sulfuric acid speleogenesis was described from Lower Kane Cave (Engel et al., 2004b), and microbial communities have also been shown to be important to sulfidic karst aquifer development (Engel, 2007). From 16S rRNA gene surveys, *Proteobacteria* are one of the most prevalent groups studied to date from hypogenic caves and karst. Most of the focus has also been on sulfur-oxidizing bacteria belonging to the classes *Epsilonproteobacteria*, *Gammaproteobacteria*, and *Betaproteobacteria* (see Chapters *Thiotrophic Bacteria*

Karst Ecosystems, Figure 4 Schematic representation of the three common cave types discussed in this article, including lava tubes, hypogenic caves, and epigenic caves. For each cave type, specific habitats are associated with microbial activities and deposits are produced because of these activities (e.g., corrosion residues in hypogenic systems).

and *Sulfur Cycle*). Stable isotope ratio systematics and radiolabeled isotope experiments have unveiled possible ecosystem function for some of the microbes in these systems (e.g., Sarbu et al., 1996; Pohlman et al., 1997; Vlasceanu et al., 1997; Humphreys, 1999a; Porter, 1999; Engel et al., 2001; Hutchens et al., 2004; Herbert et al., 2005), but more research is needed.

One of the most interesting habitats for microbes in active sulfidic caves is on cave-wall surfaces. These habitats are acidic, due in part to gypsum mineralization and microbial activity, with pH of condensation droplets on biofilms and snottites being as low as 0 (range pH 0–4) (Hose et al., 2000; Vlasceanu et al., 2000; Macalady et al., 2007) (see Chapter *Acidophiles*). Interestingly, the phylogenetic diversity of these biofilms is similar, consisting of extremophilic groups belonging to the *Proteobacteria*, actinomycetes, the bacterial candidate lineage TM6, as well filamentous fungi and protists. The biofilms from the Frasassi and Lower Kane caves have $\delta^{13}\text{C}$ values that range between -36‰ and -39‰ , suggesting that carbon within the biofilms has been produced from chemolithoautotrophy (Vlasceanu et al., 2000; Engel, 2007).

The role of microbes in iron and manganese cycling has been studied from both hypogenic and epigenic systems (e.g., Peck, 1986), although most of the current research has been done from caves that had formed from hypogenic processes but are currently under epigenic, if any, modification processes. Specifically, a diverse, metabolically active microbial communities, some of which were related to known manganese- and iron-oxidizing bacteria, are present in corrosion residues on cave-wall surfaces (Figure 4) underlying ferromanganese deposits from Lechuguilla Cave and other caves in the Guadalupe Mountains of West Texas and New Mexico (Northup et al., 2003). Among the diverse bacterial groups identified, clones belonging to both the Crenarchaeota and Euryarchaeota have been retrieved from corrosion residues (Northup et al., 2003). Similar archaeal groups have been retrieved from paleofill sediment deposits in Wind Cave in South Dakota (USA) (Chelius and Moore, 2004). Several research groups have interpreted a variety of poorly crystalline manganese oxide and hydroxide minerals in caves to be microbially induced (e.g., Northup et al., 2000).

Methanotrophic and methanogenic microbial groups, while expected to occur in some groundwater systems with high concentrations of dissolved methane (e.g., Opsahl and Chanton, 2006), have almost exclusively been studied in detail from Mobile Cave using enrichment and isolation techniques, $^{13}\text{CH}_4$ -labeling incorporation studies, and ^{13}C -DNA analysis (Vlasceanu, 1999; Hutchens et al., 2004). The contribution, if any, of methanogenic or methanotrophic activity to speleogenesis is unknown.

Epigenic caves

Because epigenic caves are geologically more common, the numbers and ranges of geobiological studies are vast.

Most studies from epigenic systems can be generally categorized into three groups: (1) those that attempt to understand the abundance, diversity, and activities of microbial communities; (2) those that attempt to relate microbial diversity to ecosystem function; and (3) those that attempt to use microbes to explain mineralogical phenomena such as precipitation and dissolution of minerals or deposits found in caves. The majority of cave and karst geomicrobiological studies can be summarized as fitting into the first category.

The health of cave and karst ecosystems can be better understood by recognizing that there is an intimate hydrologic and ecologic connection of dissolution caves between the surface and subsurface. In particular, because the geochemistry and hydrology of most karst systems respond dramatically over short periods of time following disturbances, changes in the major taxonomic and metabolic potential of a system can alert to possible water quality or sustainability issues (van Beynen and Townsend, 2005). As such, considerable effort has been made to characterize microbial communities, including heterotrophic groups, within epigenic caves and from karst aquifers (e.g., Rusterholtz and Mallory, 1994; Mahler et al., 2000; Bates et al., 2006; Goldscheider et al., 2006; Pronk et al., 2006). Results have shown that pulses of different microbial groups over time, or even from episodic inoculation events, may disturb overall ecosystem balance (e.g., Mahler et al., 2000; van Beynen and Townsend, 2005; Goldscheider et al., 2006).

Similarly, identifying the microbes in vadose zone cave habitats, such as in river sediments and from exposed cave-wall surfaces, has been done to compare pristine communities to those that may be influenced by human impact, such as from tourism (Chelius and Moore, 2004; Ikner et al., 2007). Some of the microbes found from high impact zones in tour caves are comparable to communities found in association with Paleolithic cave paintings (e.g., Schabereiter-Gurtner et al., 2002a, b, 2004; Zimmermann et al., 2005). The microbial diversity and physiological types associated with higher impact areas may be related to the increased organic matter of anthropogenic origins (from paint to lint) (Ikner et al., 2007). One of the issues pertaining to the diversity of microbes from human impacted zones is whether or not these microbes have any influence on mineral precipitation or dissolution. These microbes could negatively impact any of the natural cave processes, or even destroy cave paintings by ancient man (e.g., Schabereiter-Gurtner et al., 2004).

The mineralogy and nutrient content of rock has been suggested as the important drivers in the microbial groups that are able to colonize cave surfaces (Barton et al., 2007). Because the geomicrobiology of cave minerals, including carbonates, iron oxides, and nitrates, has been extensively studied and the studies reviewed (e.g., Jones, 2001; Northup and Lavoie, 2001; Barton, 2006; Barton and Northup, 2007), only exemplar investigations are provided here (see Chapter *Microbial Biomineralization*). Carbonate

mineralization is known to be influenced by microbes, as enrichment culturing from carbonate speleothems in Cervo Cave in Italy demonstrated that *Kocuria* spp. were precipitating carbonate at unusually high rates compared to microbes from noncave environments (Cacchio et al., 2004). Similarly, filamentous cells caused calcite to precipitate after colonizing rock surfaces (e.g., Cañaveras et al., 2006). According to Caumartin (1963), most cave sediment contains iron bacteria, and indeed, microscopy and culturing studies revealed that chemolithoautotrophic *Gallionella* spp. and heterotrophic *Leptothrix* and *Crenothrix* spp. are common (see Chapters *Leptothrix* and *Gallionella*). Encrusted sheaths and stalks of bacteria resembling modern iron-oxidizing bacterial cells have been seen from stalactites, sediments, and corrosion crusts from numerous caves (Caumartin, 1963; Peck, 1986; Onac et al., 1997; Northup et al., 2003). Despite the significance of cave nitrates in the early history of caves (i.e., for saltpeter deposits), there has been little work to advance our understanding of the role of microbes in cave nitrate formation (see Chapter *Nitrogen*). Researchers still deliberate over the degree to which bacteria, such as *Nitrosomonas* spp. and *Nitrobacter* spp., participate in the creation of the cave saltpeter deposits, although *Nitrobacter* spp. had been cultured from cave sediments in Mammoth Cave (Fliermans et al., 1974).

Karst ecosystem studies in the future

Like the discovery of life at the deep-sea hydrothermal vents more than 25 years ago (see Chapter *Hydrothermal Environments, Marine*), ongoing research in karst habitats has revealed a rich and diverse microbiota. Some of these cave and karst ecosystems are supported by chemolithoautotrophic primary productivity, thereby changing our perception that all life on Earth is dependent on photosynthesis. Caves and karst are relatively accessible habitats to study from the perspective of carbon and nutrient cycling, and discoveries are being made that relate to rock cycling (from mineral dissolution to precipitation). But, we need to move beyond observational investigations that focus on categorizing microbial communities, and instead to make important advances in understanding the geomicrobiological and biogeochemical roles of microbes in cave and karst to address the rates and mechanisms controlling microbial ecophysiology and ecosystem functioning. This methodology exists and so we should expect that exciting new discoveries will be made with continued technological advances. One outcome from these efforts will be an increase in our knowledge of cave and karst biodiversity to better protect and conserve these novel geological and ecological systems.

LATERAL GENE TRANSFER

Hans-Joachim Fritz
University of Göttingen, Göttingen, Germany

Synonyms

Horizontal gene transfer

Definition

The use of the term in the literature is not entirely unambiguous. For the purpose of this entry, lateral gene transfer (LGT) is defined as the stable transfer of genetic material (DNA, possibly RNA) from one organism to another where the two organisms belong to lineages which are genetically too distant to allow a mutual act of homologous recombination.

Introduction

Vegetative proliferation is characterized by a vertical line of genetic transfer from one cell to two daughter cells. Upon zygote formation, in contrast, sexual reproduction mixes the genetic outfit of two parent organisms. Fertile offspring, however, is only produced if the two parents are genetically close enough to allow for gamete formation (i.e., meiosis with mandatory homologous recombination) in the offspring. This limit defines a breeding pool which, in turn, can serve as a useful approach to the term “species.”

In the bacterial and the archaeal domains of life, the species concept is much more contentious – for reasons partly illustrated by this article. Nevertheless, the homologous recombination criterion can be upheld at least in cases like *Escherichia coli*, in which genetic traits are transferred by conjugation between two pre-existing cells. Conjugation proceeds by transient cell fusion between an Hfr⁺ and an Hfr[−] cell, followed by physical transfer of

DNA from the former to the latter, followed by homologous recombination. Natural transformation in *Streptococcus pneumoniae* provides a similar example.

Against this backdrop, LGT can be viewed as any transfer of genetic material between two organisms that are separated by the homologous recombination barrier. This criterion separates, for example, *E. coli* from the closely related *Salmonella typhimurium*; in cases with no known system of homologous recombination, the criterion has to be replaced by corresponding and somewhat arbitrary measures such as sequence distance. There are two hallmarks of LGT which may be detected simultaneously or alternatively in any particular single case.

1. Presence of genes in a genome that are not present in genomes of otherwise closely related organisms.
2. Topologically different branching patterns obtained in attempts to delineate phylogenetic relationships between a host of lineages, based on sequence comparisons within more than one set of (seemingly) orthologous genes.

Other, less clear-cut indicators of LGT include G/C content and codon usage that deviate from those of the bulk genome and also physical gene linkages that differ from those observed with close relatives.

These statements together make it immediately understandable why the intensity of the debate of LGT developed in parallel with the unfolding of the genome analysis era that followed the publication of the *Haemophilus influenzae* sequence in 1995 (Fleischmann et al., 1995). To date, several hundred genomic sequences have been determined – mostly of bacteria and archaea. By far most of the knowledge we have about LGT concerns the bacterial and archaeal domains (including trans-domain transfer) and it is not entirely clear to which extent this fact reflects (non)availability of the necessary mechanisms in the different domains and to which simple numerical preponderance of sequenced prokaryotic

genomes. The following discussion focuses on LGT in bacteria and archaea (and between bacteria and archaea). Establishment of endosymbiosis can be regarded as an extreme case of LGT; because it is such an exception with respect to mechanism and frequency of occurrence, it is not covered here.

Mechanisms

Mechanistically, LGT can be divided into two consecutive steps:

1. Introduction of foreign DNA into the recipient cell. (In the following, the alternative option of RNA being introduced is no longer explicitly mentioned.)
2. Stable establishment of the transferred DNA as part of the genetic outfit of that cell.

Step 1: DNA can arrive in a recipient cell as the result of conjugation (i.e., as a plasmid or genome fragment) of phage infection (i.e., as a phage genome, in particular of a transducing phage carrying genes of a former host) or by physical uptake (i.e., any piece of naked DNA).

Step 2: The newly arrived DNA can either be degraded or stably established in the cell in parts or *in toto* by any of the following mechanisms: (i) independent replication as an episome (plasmids, certain kinds of lysogenic phage such as *E. coli* P1); (ii) transposition (transposon, IS-elements or the like) from the entering DNA molecule to the recipient's chromosome (or other residing replicon); (iii) site-specific recombination as seen in lysogenic phage such as phage Lambda; (iv) illegitimate recombination (a term collectively used for a number of mechanisms that require no or only very short stretches of high sequence similarity between the two recombining molecules).

Note that in order for any combination of Steps 1 and 2 to qualify as LGT, the criterion of the homologous recombination barrier has to apply for the lineage of the donor and the receptor of the DNA (compare above: Definition).

Plausibly, the acquisition of genetic traits through LGT is limited by incompatibilities of gene expression signals present in the transferred DNA with cognate proteins (RNA polymerases, repressors, gene activators) or other macromolecular components of the gene expression apparatus of the recipient cell (e.g., rRNA).

Some selected cases

Extent of LGT

Porwollik and McClelland (2003) have used comparative genomics and microarray analysis to determine the extent to which LGT participated in shaping the genomes of different *Salmonella enterica* serovars. They come to the conclusion that almost one quarter of the entire *S. enterica* sv. *Typhimurium* genome may have been introduced by LGT.

Trans-domain LGT

In bacteria and eukarya, the repair of DNA-uracil residues (pre-mutagenic DNA lesions resulting from spontaneous

hydrolytic deamination of DNA cytosine residues) is almost invariably initiated by a family 1 UDG enzyme (UDG: Uracil DNA Glycosylase). On the other hand, no family 1 UDG gene has been discovered to date in any archaeal genome. For archaea, UDGs of families 4 and 5 seem to be typical. The genome of *Thermus thermophilus*, a Gram-negative, extremely thermophilic bacterium, almost uniquely for a bacterium, contains no gene for a family 1 UDG, but one gene each for a UDG enzyme of family 4 and 5 (Starkuviene and Fritz, 2002; Henne et al., 2004). This highly unusual finding is most simply explained by lateral transfer of the family 4 and family 5 genes into *T. thermophilus* (or an ancestor thereof) across the domain barrier, followed by loss of the formerly residing family 1 gene whose activity had been made redundant by the LGT event.

Consequences and summary

Lateral gene transfer lies at the heart of some pressing practical problems, among them is the rapid emergence of multiply-resistant pathogens under the selection pressure of widespread (and sometimes inappropriate) use of antibiotics. Naturally spreading promiscuous plasmids of overlapping host range, combined with DNA transposition are arguably the major contributors to that process. The spread of pathogenicity islands is a similar example. More fundamentally, the nature and extent of LGT shakes the entire evolutionary concept of common descent and, along with it, the usefulness of its iconographic representation, the tree of life. Rather, the bacterial and the archaeal domains of life together form a densely woven genetic network along which smaller or larger packages of genes can move with a high enough degree of independence to leave frequent and conspicuous traces of this process in genome structures. Different genes may have come together in a common genome as the result of profoundly different ancestry trajectories. This mosaic nature of the genome potentially frustrates any attempt of deriving stringent phylogenetic relationships at the organismal level from DNA sequence data. As a substitute of low resolution, one may operate with the consensus tree topology one may find for the large majority of genes present in the genomes under consideration.

LEPTOTHRIX

David Emerson
Bigelow Laboratory for Ocean Sciences, West Boothbay Harbor, ME, USA

Definition

Leptothrix describes a genus of bacteria that have long been recognized as important in the biological oxidation of iron and manganese (van Veen et al., 1978). It is one of several genera that may be referred to as the “iron bacteria.” At present, there are five recognized species: *L. ochracea*, *L. discophora*, *L. cholodnii*, *L. lopholea*, and *L. mobilis* (Garritty et al., 2004). The genus is in the class Betaproteobacteria. The members of this genus are recognized for the production of an extracellular tubular sheath. The cells typically grow as chains of cells within the sheath, which they excrete as they grow. It is common for the sheaths to be coated in Mn oxides or Fe oxyhydroxides. *L. ochracea* is perhaps the most commonly recognized *Leptothrix* spp. due to copious production of very straight, iron encrusted sheaths. This species has never been cultivated in the laboratory and its exact relationship to other members of the genus is not known. Circumstantial evidence suggests that it is capable of lithotrophic growth using Fe(II) as sole energy source; however, this has not been proven. The evidence stems from its requirement for Fe-rich waters to grow. Typically, these are wetlands, springs, water wells, and like environments where anoxic groundwater enriched in Fe(II) comes into contact with air. Another interesting feature of *L. ochracea*, and also indicative of its use of iron as an energy source, is that only a small percentage (estimated at about 10%) of the sheaths contain cells during active growth (Figure 1). An interesting facet of these metal encrusted sheaths is that they can be preserved in the fossil record (Hofmann and Farmer, 2000). The other species of *Leptothrix* have been cultured in the laboratory and identified using classical microbiological techniques. All of these latter species are heterotrophic organisms utilizing organic carbon sources for growth. To date there is no compelling evidence that they are either lithoautotrophic or mixotrophic. They are typically found in wetlands and other aqueous habitats. Proteins with enzymatic activity for Mn-oxidation have been found in *L. discophora* and *L. cholodnii* (Adams and Ghiorse, 1987; Emerson and Ghiorse, 1992). Both species also accumulate Fe-oxyhydroxides on their sheaths, and a gene has been identified in *L. discophora* that is associated with iron oxidation (Corstjens et al., 1992). These Mn- or Fe-oxidizing

Leptothrix, Figure 1 *Leptothrix ochracea* from a wetland iron seep, note the tubular sheaths that are composed primarily of Fe-oxide. The lower panel shows a filament of cells inside one of the sheaths that has been stained with a DNA-fluorescent dye. The bar = 5 μ m.

proteins appear to be secreted from the cell into the surrounding sheath, the site of metal oxidation. The sheath of *L. cholodnii* is a complex fibrillar polymer consisting primarily of polysaccharides with a high concentration of the amino acid cysteine (Emerson and Ghiorse, 1993a). The fibrils are held together by extensive disulfide bonding, making it a very resilient structure (Emerson and Ghiorse, 1993b). A novel cysteine glycoconjugate is the primary building block of the sheath (Makita et al., 2006).

MAGNETOTACTIC BACTERIA

Mihály Pósfai
University of Pannonia, Veszprém, Hungary

Definition

Magnetotactic bacteria (MTB) are a diverse group of Gram-negative, motile prokaryotes that align and migrate along the geomagnetic field. This magnetotactic behavior is based on intracellular organelles called magnetosomes, which are inorganic nanocrystals of either magnetite (Fe_3O_4) or greigite (Fe_3S_4), surrounded by a lipid bilayer membrane. The magnetosomes are typically arranged in one or more chains, conveying a magnetic dipole moment to the cell (Figure 1). Magnetotaxis is thought to be beneficial for the cell for finding its optimum position in vertical concentration gradients in aquatic habitats.

History

Bacteria that responded to magnetic fields were discovered independently by Bellini (1963) and Blakemore (1975), who coined the term magnetotaxis and noted the presence of crystals in the cells. Intracellular magnetite was identified and the physics of magnetotaxis was described by Frankel et al. (1979). Iron sulfide-producing MTB were found in 1990 (Mann et al., 1990; Farina et al., 1990). The ecology of MTB and the structures and morphologies of the crystalline components of magnetosomes have been widely studied since the discovery of MTB. In the past decade, significant progress has been made in elucidating the molecular, biochemical, and genetic bases of magnetosome formation (Schüler, 2007).

Ecophysiology

MTB are ubiquitous in both marine and freshwater aquatic habitats, where suboxic or anoxic conditions prevail, and

dissolved iron is available. Because of their fastidious nature, only a few strains are available in pure culture. With one exception, all strains in pure culture have a respiratory form of metabolism. All known MTB are microaerophiles (they require a certain amount of oxygen for growth, but exhibit a negative tactic and/or growth response to atmospheric concentrations of oxygen) or anaerobes or facultatively anaerobic microaerophiles (Bazylinski and Frankel, 2004). The physiology of MTB appears to dictate their ecology: since MTB derive energy from the proximity of oxidants and reductants, magnetite-producing organisms occur in largest numbers (up to 10^5 cells/ml) in layers at or near the oxic–anoxic interfaces (OAI) of chemically stratified habitats. Iron sulfide-producing bacteria live below the OAI under anaerobic conditions (Simmons et al., 2004). Whereas magnetite-producing bacteria occur virtually in all types of water bodies, sulfide-producing organisms have been found in marine habitats only. Considering the large amount of iron concentrated in magnetosomes (10^{-15} to 10^{-13} g Fe per cell) and the estimated population density of MTB at and below the OAI, MTB are likely to contribute significantly to the flux of reduced Fe to sediments in chemically stratified marine basins.

Magneto-aerotaxis

Magnetotaxis means active motion guided by the magnetic field. MTB passively orient along the geomagnetic field and actively swim by means of flagella. A key element of magnetotaxis is that the cell should possess a large enough magnetic dipole moment to overcome the disorientating effects of thermal motions and be aligned parallel to the magnetic field. In the geomagnetic field, the magnetic energy of magnetotactic cells is typically ten times larger than thermal energy, which means that the cell can migrate along the field at 90% of its forward speed (Frankel et al., 1979).

Magnetotactic Bacteria, Figure 1 A cell of *Magnetospirillum gryphiswaldense* that contains a single chain of magnetite magnetosomes.

“Polar” and “axial” magnetotaxis are distinguished (Frankel et al., 1997). Polar magnetotaxis is displayed by MTB that swim persistently toward one of the poles of a bar magnet under oxic conditions. Those that swim toward the “south” pole of a magnet have North-seeking polarity, since they would swim northward in the geomagnetic field. MTB from the northern hemisphere are predominantly North-seekers, whereas those from the southern hemisphere are predominantly South-seekers (Bazylinski and Frankel, 2004).

The observation of polar magnetotaxis led to the idea that MTB are guided by the geomagnetic field to less oxygenated regions. Since the geomagnetic field is inclined downward from the horizontal in the northern hemisphere and upward in the southern hemisphere under oxic conditions the cells with polar magnetotaxis swim downward in both hemispheres (Bazylinski and Frankel, 2004). However, if the cell is in a reducing environment, it reverses the direction of flagellar rotation and migrates upward. Since the motion of the cell is determined by both the magnetic field and the oxygen tension, the term “magneto-aerotaxis” was introduced (Frankel et al., 1997).

Axial magnetotaxis means that the axis of motion is determined by the magnetic field but its direction is not. As the cell swims, it samples the oxygen concentration and compares it with that in the recent past. Cells moving toward the optimal habitat have a decreased probability of reversing the sense of flagellar rotation, whereas those that are moving away from the optimal oxygen concentration have an increased probability of reversing the sense of flagellar rotation and thus their swimming direction (Frankel et al., 1997). The magneto-aerotactic response provides an

efficient mechanism for MTB to find the OAI in their chemically stratified habitats.

Mineralogy and magnetism

Magnetotaxis relies on intracellular grains of iron oxide or sulfide minerals. Magnetite (Fe_3O_4) is the only iron oxide mineral that has been described to date from magnetotactic cells. The sulfide-producing cells use greigite (Fe_3S_4) for navigation, but they also may contain nonmagnetic mackinawite (FeS) that rapidly converts to greigite through a solid-state phase transition (Pósfai et al., 2007).

Magnetite produced by MTB is chemically pure Fe_3O_4 , in contrast to grains from rocks that usually contain other transition metals besides iron. Structurally, the nanocrystals are either perfect or contain twin boundaries. The morphologies of magnetite magnetosomes are typically highly regulated, strain-specific, and in many cases, unusual for a mineral with cubic symmetry (Pósfai et al., 2007). Whereas magnetotactic spirilla contain cubooctahedral crystals, vibrio and cocci typically produce magnetite with prismatic habits (Figure 2a). Large, rod-shaped cells tend to contain arrowhead- or bullet-shaped magnetite crystals (Bazylinski and Frankel, 2004).

The sizes and shapes of magnetosomes are critical for magnetotaxis. Isolated, isometric magnetite crystals with diameters smaller than ~ 30 nm are superparamagnetic, i.e., they do not have a permanent magnetic moment. Crystals with diameters from ~ 30 to ~ 120 nm are magnetic single domains at room temperature, whereas grains larger than ~ 120 nm contain two or more magnetic domains, reducing the net magnetic moment of the crystal. Most magnetosomes are in the single-domain range, allowing the assembly of a highly efficient internal compass that consists of a chain (or chains) of single-domain magnets. Interactions between neighboring particles in chain configurations ensure that even those magnetite particles that are small enough to be superparamagnetic or large enough to contain two or more magnetic domains if they were isolated are also constrained to be single domains (Dunin-Borkowski et al., 2001). Since elongated particles are arranged with their axis of elongation (which typically coincides with their crystallographic easy magnetization axis) parallel to the chain of magnetosomes, shape anisotropy constrains the magnetic flux lines to be parallel to the axis of motility. Thus, in most magnetite-producing cells the effects of particle size, shape and magnetocrystalline anisotropy, and magnetostatic interactions among particles in chains combine to produce the possible largest magnetic moment (Figure 2b) (Pósfai et al., 2007).

The sizes, shapes, and orientations of iron sulfide magnetosomes are less distinct than those of magnetite magnetosomes. Greigite magnetosomes typically contain planar defects, as a result of an incomplete solid-phase transformation from mackinawite to greigite. The shapes and orientations of the crystals are random,

Magnetotactic Bacteria, Figure 2 (a) Electron micrograph of two double chains of elongated magnetite magnetosomes from a freshwater magnetotactic coccus. (b) Magnetic induction map of a similar double chain of magnetite magnetosomes, obtained from electron holograms.

resulting in poorer confinement and greater variability in the directions of the magnetic induction lines in the cells than in magnetite-bearing bacteria. Remarkably, despite the different crystal structures, orientations, and arrangements of ferrimagnetic crystals, the magnetic moments of different cells are fairly constant (Pósfai et al., 2007), thereby satisfying the requirement for magnetotaxis.

Cell biology and genomic analyses

Magnetic enrichments have shown great morphological and ultrastructural diversity of MTB from a wide variety of aquatic environments. Magnetite-producing morphotypes include spirilla, cocci, vibrios, and rods of various sizes, moving at speeds ranging from 40 to 1,000 $\mu\text{m/s}$. A unique, greigite-producing magnetotactic organism, the “multicellular magnetotactic prokaryote” (MMP) consists of 15–45 cells organized around an internal acellular compartment (Keim et al., 2004). The aggregated cells of the MMP move together as one unit, with the coordinated motion of flagella on the outside of the cells.

The highly controlled, strain-specific properties of magnetite magnetosomes and their chains indicate that biomineralization is under genetic control, executed by specific proteins in the magnetosome membrane. Many details of magnetosome formation have been elucidated by studies of the biochemistry of the magnetosome membrane and genomic analyses of MTB. Workable genetic systems have been developed for two *Magnetospirillum* strains: *M. magnetotacticum* AMB-1 and *M. gryphiswaldense* MSR-1 (Jogler and Schüller, 2007). By genetic manipulation, including the generation of mutants and the expression of magnetobacterial genes in other hosts, the major steps of magnetite biomineralization have been identified in these systems. Magnetite nucleation is preceded by the formation of vesicles, which are invaginations of the cytoplasmic membrane (Komeili et al., 2006). Dissolved ferrous or ferric iron is transported into the cell by an unknown uptake

system. Magnetosome membrane proteins (MamB/MamM) are involved in the transport of ferrous iron from the cytoplasm into the magnetosome vesicle, and then magnetite formation is activated by another protein (MamA). Within the vesicle, iron is oxidized and magnetite nucleation is triggered by the Mms6 protein. The least known aspect of the biomineralization process is the control over the distinct crystal morphology. The vesicles containing fully developed magnetite crystals are anchored to a filamentous cytoskeletal structure by the MamJ protein, resulting in an ordered magnetosome chain (Scheffell et al., 2006). Genomic analyses revealed that the genes that encode the magnetosome proteins are clustered in a 130 kb region, representing a “magnetosome island.” This genomic island appears to be conserved among different *Magnetospirillum* strains and, to a lesser degree, in a magnetotactic coccus (Jogler and Schüller, 2007), raising the question of whether the “magnetosome island” is a universal feature of MTB.

Diversity

The term “magnetotactic bacteria” does not refer to a taxonomical unit. All known MTB belong to various groups within the domain Bacteria. Most magnetotactic microorganisms that are available in pure culture are affiliated with the *Alphaproteobacteria*, including *M. magnetotacticum* and *M. gryphiswaldense*, a marine vibrio (MV-1), and a coccus (MC-1). In addition to the cultivated strains, 16S rRNA analysis of magnetic enrichments from many freshwater and marine samples revealed that a variety of magnetite-producing morphotypes are likely affiliated with the *Alphaproteobacteria* (Amann et al., 2007). Two magnetite-producing candidate species, “*Magnetobacterium bavaricum*” and “*Magnetotacticum bremense*,” are affiliated with the *Nitrospira* phylum.

Sulfide-producing MTB could not have been cultured to date, but a multicellular organism was found to be closely related to the dissimilatory sulfate-reducing

bacteria within the *Deltaproteobacteria*. Another sulfide-producing MTB was assigned to *Gammaproteobacteria*. These findings may suggest that magnetotaxis based on iron oxide and sulfide nanoparticles evolved independently; however, a magnetite-producing, sulfate-reducing organism (*Desulfovibrio magneticus* strain RS-1) is also affiliated with the *Deltaproteobacteria* (Amann et al., 2007).

The diversity of MTB indicates that magnetotaxis evolved independently in several phylogenetic groups. On the other hand, the discovery of a potentially mobil “magnetosome island” in the genome of magnetite-producing MTB could suggest that the trait of magnetotaxis was spread by lateral gene transfer among the various groups of MTB.

Magnetofossils, paleomagnetism

After MTB die, their intracellular magnetite or greigite particles are deposited in the sediment. If diagenetic conditions are favorable, the magnetosome crystals can be preserved as magnetofossils. Magnetofossils have been identified on the basis of the special properties of magnetosome crystals, including a narrow crystal size distribution, characteristic morphologies, chemical purity and, in some cases, chain configurations. Ferrimagnetic nanocrystals presumably originating from MTB have been described from a variety of sedimentary rock types, including clays, carbonates, marls, and evaporites. The magnetofossil record extends from present-day marine and lake sediments to the Cretaceous and with lesser certainty to the late Archean (Kopp and Kirschvink, 2008).

MTB carry a primary remanent magnetization, since they are aligned with the geomagnetic field, presumably even after cell death and burial in the sediment. Because magnetofossils are single magnetic domains, they have an optimized magnetic stability and can be important carriers of paleomagnetic information. Magnetofossils can serve as environmental proxies because MTB live under specific redox conditions. They can also be markers of ancient life, albeit dubious ones, as illustrated by a lengthy debate over whether nanocrystalline magnetite particles in the Martian meteorite ALH84001 represent magnetofossils or had formed inorganically (Winklhofer and Petersen, 2007).

Nanotechnological applications

Magnetic nanoparticles are widely used in technological applications, such as in spintronics, in magnetic inks, in high-density magnetic memory devices, and in medical applications (as contrast agents in magnetic resonance imaging and as magnetic carriers for drug targeting and delivery). Magnetite crystals produced by MTB have uniform sizes and shapes and can be separated from disrupted cells by magnetic methods with their magnetosome membrane intact. The membrane-bound bacterial nanoparticles have a large specific surface area and are well dispersed in aqueous solutions. Antibodies or proteins can be immobilized on the magnetosome membrane, producing

functionalized magnetic nanoparticles (Matsunaga and Arakaki, 2007). Since bound and free analytes can be separated in a magnetic field, bacterial nanoparticles have been used for the rapid and sensitive detection of small molecules, including environmental pollutants, hormones, and toxic detergents. Immunomagnetic particles are also useful for sorting target cells from cell suspensions using a permanent magnet, and for using them in high-performance DNA/mRNA recovery and DNA discrimination analysis (Matsunaga and Arakaki, 2007).

Summary

MTB provide a fascinating example of microbial biomineralization and motivate interdisciplinary research at the junctions of biology, mineralogy, geology, geochemistry, and physics. The molecular and genetic bases of magnetic nanocrystal formation by MTB are now beginning to be understood. The results of research on MTB will be useful for understanding biomineralization processes and magnetic sensing mechanisms in more complex organisms, and for designing nanotechnological applications of bacterial nanocrystals.

Definition

Rhodochrosite. Manganese(II) carbonate (MnCO_3 ; trigonal, calcite structure), named after the greek word for “rose-colored.” It was named as the state mineral of Colorado (USA) in 2002. Complete solid solution formation with calcite occurs at low temperatures (Böttcher, 1998), the “Ca-rhodochrosites” or “pseudo-kutnahorites” (Mucci, 2004).

Kutnahorite. Manganese(II)-calcium carbonate ($\text{CaMn}(\text{CO}_3)_2$; trigonal; ordered dolomite structure), named after the location KutnoHora (Peacor et al., 1987). Although physicochemically stable at low temperatures

with respect to equally composed solid-solutions (Mucci, 2004), it is not formed in sediments, and only known from high-temperature hydrothermal and metamorphic environments.

Rambergite. Manganese(II) sulfide ($\mu\text{-MnS}$; hexagonal), named after the mineralogist Hans Ramberg, is found as authigenic product in anoxic sediments of the Baltic Sea (Böttcher and Huckriede, 1997; Burke and Kemp, 2002).

Alabandite. Manganese(II) sulfide ($\alpha\text{-MnS}$, cubic), named after the location Alabanda, Turkey, is found in sediments as minor intergrowth with rambergite (Lepland and Stevens, 1998).

Manganese carbonate formation in suboxic/anoxic sediments

Mixed manganese–calcium carbonates, with minor incorporation of magnesium and divalent iron, are formed in (brackish-marine) sediments as authigenic products of suboxic and anoxic early diagenesis, in the Baltic Sea deeps and the Panama Basin. Significant sedimentary Ca-rhodochrosite accumulation requires manganese(IV) dioxide pre-enrichment at the sediment–water interface by episodic water column oxidation, as shown for the temporarily euxinic deeps of the Baltic Sea (Huckriede and Meischner, 1996). The required dissolved carbonate species are formed in the pore water upon mineralization of organic matter, and aqueous Mn^{2+} is derived from microbial or chemical reduction of manganese(III, IV) oxides as electron acceptors (e.g., Banfield and Nealson, 1997). The carbonates occur as kidney-shaped globules, as overgrowth on foraminifers, detrital carbonates, and microbial cells or as idiomorphic crystals, depending on the micro-environment. Experimental studies reveal that the composition of manganese-rich carbonates is controlled by the pore water composition, the abundance of carbonate surfaces, and the presence of inhibitors (Böttcher, 1998; Mucci, 2004). Under equilibrium conditions, natural anoxic pore waters are in the stability field of coexisting rhodochrosite and iron sulfides (Figure 1), and no manganese sulfide should be formed during typically zoned early diagenetic processes.

Manganese sulfide formation in anoxic sediments

The only places worldwide where sedimentary manganese sulfides have been found so far are the Baltic Sea anoxic deeps (e.g., Baron and Debyser, 1957). Idiomorphic MnS (Figure 2) is associated with organic matter, Ca-rhodochrosite, and iron sulfides (Böttcher and Huckriede, 1997; Lepland and Stevens, 1998). Although MnS has been obviously formed under slow diffusion-controlled conditions where rhodochrosite formation was chemically inhibited, the exact process is still under debate. Occurrence of Ca-rhodochrosite replacing hexagonal MnS (Burke and Kemp, 2002) indicates possible readaptation of the metastable sedimentary system toward equilibrium conditions.

Conclusion

Sedimentary authigenic manganese(II) carbonate minerals, especially investigated in the nowadays brackish-marine

Baltic Sea, are indicative of biogeochemical early-diagenetic processes in manganese-rich environments. They have gained a lot of attention in the past 2 decades because of their proxy potential for specific hydrological conditions leading to euxinic water column turnover or glacial-interglacial cycles that are controlled by climate change (e.g., Lepland and Stevens, 1998; Gingele and Kasten, 1994). One of the many open questions within the biogeochemistry and geomicrobiology of manganese in sediments is about the conditions leading to the metastable formation and preservation of manganese(II) sulfides. An interpretation of water profiles in sediments with high manganese load point toward complex interactions between chemical inhibitors, microbial processes, and rates of (temporary) mineral formation processes.

SULFUR ISOTOPES

Michael E. Böttcher
 Leibniz Institute for Baltic Sea Research, Warnemünde,
 Germany

Synonyms

Radioactive sulfur isotopes; Stable sulfur isotopes

Definition

Sulfur. A chemical element that is one of the constituents of living organisms and of the Earth.

Isotopes. Isotopes are different nuclear forms of the same element. For a given element, a constant number of protons but different numbers of neutrons in the nucleus correspond to different isotopes. Sulfur of standard atomic mass 32.065 u has 18 isotopes, most of which are not stable and undergo radioactive decay.

Stable sulfur isotopes. Stable isotopes are isotopes that do not decay within an experimentally observable time frame. Stable isotopes have essentially the same chemical characteristics and, therefore, their behavior is chemically almost identical. The different masses lead to isotope fractionation in chemical, physical, and especially biological reactions. Four stable isotopes occur in nature: ^{32}S (95.02%), ^{33}S (0.75%), ^{34}S (4.21%), and ^{36}S (0.02%) (Hoefs, 2008). Typically, the ratio of the two most

abundant sulfur isotopes is measured and presented in the conventional δ notation as opposed to the Vienna-Canyon-Diablo-Troilite (V-CDT) standard ($\delta^{34}\text{S}$ values per mil versus the V-CDT standard). In aerobic surface environments, the sulfur isotopic composition of sulfate is often used for source identification (e.g., anthropogenic versus geogenic sulfate in rain, river, and ground waters (e.g., Clark and Fritz, 1997). Only recently has the fractionation of the minor isotopes ^{33}S and ^{36}S also been introduced into sulfur isotope biogeochemistry (e.g., Farquhar et al., 2003).

Radioactive sulfur isotopes. Sulfur has 14 unstable isotopes. Radioactive sulfur with mass 35 is formed in the atmosphere from cosmic ray spallation of argon with mass 40 and has a half-life of 87 days. Therefore, it is used in hydrological studies of biologically less active surface environments. ^{35}S -labeled sulfur compounds are used in experiments to determine microbial and chemical sulfur turnover, upon microbial dissimilatory sulfate reduction, for instance (e.g., Kallmeyer et al., 2004). The other radioactive sulfur isotopes are all short-lived.

Fractionation of stable sulfur isotopes

Sulfur isotopes are fractionated upon microbial and abiotic sulfur transformations and the isotope signal may be preserved in sedimentary sulfide- and sulfate-bearing solids, organic matter, and to a minor extent, elemental sulfur (e.g., Canfield, 2001; Amend et al., 2004). The majority of geochemical and microbial studies on sulfur isotopes have so far focused on the fractionation of ^{32}S to ^{34}S . The most important isotope discrimination step occurs during dissimilatory reduction of dissolved sulfate within the bacterial cell. The overall change in the valence state of sulfur by pure cultures leads to hydrogen sulfide that is enriched in the lighter isotope by up to about 50 per mil when compared to sulfate (Figure 1). The magnitude of isotope discrimination depends on conditions such as cellular sulfate reduction rate, substrate and sulfate concentrations, and the organisms (e.g., Kaplan and Rittenberg, 1964; Chambers and Trudinger, 1979; Bolliger et al., 2001; Canfield, 2001; Amend et al., 2004). A maximum fractionation upon sulfate reduction of up to about 70 per mil is obtained from pore water modeling in natural environments (e.g., Wortmann et al., 2001), which is close to the value predicted for thermodynamic equilibrium conditions. Further partial or complete oxidation of hydrogen sulfide is associated with only small isotope discrimination, but may lead to the formation of (metastable) sulfur intermediates. The bacterial disproportionation of these compounds (e.g., elemental sulfur, thiosulfate, sulfite) yields hydrogen sulfide that is further enriched in the lighter isotope compared with the original sulfide (Figure 1).

This may contribute to the magnitude of isotope partitioning found in shallow natural environments and the fossil record (Canfield, 2001).

Sulfur Isotopes, Figure 1 Synthesis of low temperature experimental studies on microbial and abiotic S-34/S-32 fractionations upon sulfur transformations and transport (Amrani and Aizenshtat, 2004; Böttcher and Piel, 2008; Böttcher et al., 1998; Bolliger et al., 2001; Canfield et al., 1998; Chambers and Trudinger, 1979; Cypionka et al., 1998; Fry, 2006; Habicht et al., 1998; Kaplan and Rittenberg, 1964).

Conclusions

Stable sulfur isotope partitioning preserved in the sedimentary record may serve as a proxy for microbial sulfur cycling (e.g., Amend et al., 2004; Canfield, 2001). One of the many open questions within the biogeochemistry of stable sulfur isotopes regards the conditions leading to the sulfur isotope extremes in sediments, which differ from experimental results with modern bacterial cultures. New insights are expected to derive from experiments carried out under boundary conditions that more closely approach natural environments, the consideration of new cultures, and the application of multi-isotope approaches including analysis of the minor sulfur isotopes (e.g., Farquhar et al., 2003) and sulfur-bond oxygen (e.g., Brunner et al., 2005).

SYMBIOSIS

Sharmishtha Dattagupta¹, Frank Zielinski²

¹University of Göttingen, Göttingen, Germany

²Helmholtz Centre for Environmental Research (UFZ), Leipzig, Germany

Definition

A close, prolonged physical and/or metabolic association between two or more distinct organisms.

Introduction

Most living organisms interact intimately with one or more symbiotic partners that are often vital for their health and survival. Symbiotic organisms are important ecosystem engineers (e.g., corals); they significantly impact biogeochemical cycles (e.g., legumes), and they contribute substantially to geological processes such as rock weathering (e.g., lichens and mycorrhizal fungi). Moreover, symbioses have played a crucial role in the origin and diversification of eukaryotic life.

Important terms and concepts

Symbioses are categorized as being mutualisms, where both organisms involved benefit, commensalisms, where

one organism benefits and the other remains unaffected, or parasitisms, where one organism benefits but the other is harmed. When metabolite exchange occurs between symbiotic organisms, it is called syntrophy. Syntrophic interactions among microorganisms can drive otherwise thermodynamically unfavorable reactions forward due to the removal of metabolic end products.

In symbiosis terminology, the smaller symbiotic partner (often a microbe) is referred to as the “symbiont,” whereas the larger partner is called the “host.” In ectosymbioses, the symbiont is located on the external surface of the body of its host, whereas in endosymbioses, the symbiont lives inside the body of its host, either within its cells or in extracellular spaces. Symbioses vary from being *obligate*, where the interaction is critical for the survival of at least one organism involved, or *facultative*, where the organisms involved can also survive independently of each other. The method by which the host acquires its symbionts is called the mode of transmission. In *vertical transmission*, symbionts are inherited from the previous generation, as they are passed from the parent to the egg or embryo. In *horizontal transmission*, symbionts are acquired anew in each generation either from co-occurring hosts or from the environment.

History

Symbiosis is derived from the Greek words, *syn* (together) and *bio* (life). German biologist Anton de Bary is usually credited with coining the term in the mid-nineteenth century, though an equally important contribution was made by his contemporary, Albert Bernhard Frank (who instead used the term *symbiotism*) (Sapp, 2004). De Bary introduced the term to discuss lichens, which he discovered were composites of algae and fungi. Frank, on the other hand, reported on the intimate association between fungi and roots of forest trees, which he named “mykorrhiza” (fungus root). De Bary defined symbiosis as the phenomenon in which “unlike organisms live together” and explicitly included parasitism in his definition (Kutschera and Niklas, 2005). Therefore, the original definition of symbiosis was meant to include the entire gamut of close and long-term associations between two distinct organisms, irrespective of the benefit or harm caused by the interaction. The historical definition of symbiosis was eventually replaced in many modern textbooks with a more restricted definition that included only mutually beneficial associations, making the meaning of symbiosis synonymous with “mutualism” (Wilkinson, 2001). Unfortunately, research on symbioses has been fraught with confusion and controversies, in part due to the two coexisting definitions of the term (Smith, 2001; Sapp, 2004).

Conceptually, the original definition of symbiosis makes more sense in light of the fact that “benefit” is difficult to quantify in studies of symbioses (Smith, 2001). Cost-benefit ratios of symbioses can change with environmental conditions. For example, symbiotic mycorrhizal

M

MAGNETOTACTIC BACTERIA

Mihály Pósfai
University of Pannonia, Veszprém, Hungary

Definition

Magnetotactic bacteria (MTB) are a diverse group of Gram-negative, motile prokaryotes that align and migrate along the geomagnetic field. This magnetotactic behavior is based on intracellular organelles called magnetosomes, which are inorganic nanocrystals of either magnetite (Fe_3O_4) or greigite (Fe_3S_4), surrounded by a lipid bilayer membrane. The magnetosomes are typically arranged in one or more chains, conveying a magnetic dipole moment to the cell (Figure 1). Magnetotaxis is thought to be beneficial for the cell for finding its optimum position in vertical concentration gradients in aquatic habitats.

History

Bacteria that responded to magnetic fields were discovered independently by Bellini (1963) and Blakemore (1975), who coined the term magnetotaxis and noted the presence of crystals in the cells. Intracellular magnetite was identified and the physics of magnetotaxis was described by Frankel et al. (1979). Iron sulfide-producing MTB were found in 1990 (Mann et al., 1990; Farina et al., 1990). The ecology of MTB and the structures and morphologies of the crystalline components of magnetosomes have been widely studied since the discovery of MTB. In the past decade, significant progress has been made in elucidating the molecular, biochemical, and genetic bases of magnetosome formation (Schüler, 2007).

Ecophysiology

MTB are ubiquitous in both marine and freshwater aquatic habitats, where suboxic or anoxic conditions prevail, and

dissolved iron is available. Because of their fastidious nature, only a few strains are available in pure culture. With one exception, all strains in pure culture have a respiratory form of metabolism. All known MTB are microaerophiles (they require a certain amount of oxygen for growth, but exhibit a negative tactic and/or growth response to atmospheric concentrations of oxygen) or anaerobes or facultatively anaerobic microaerophiles (Bazylinski and Frankel, 2004). The physiology of MTB appears to dictate their ecology: since MTB derive energy from the proximity of oxidants and reductants, magnetite-producing organisms occur in largest numbers (up to 10^5 cells/ml) in layers at or near the oxic–anoxic interfaces (OAI) of chemically stratified habitats. Iron sulfide-producing bacteria live below the OAI under anaerobic conditions (Simmons et al., 2004). Whereas magnetite-producing bacteria occur virtually in all types of water bodies, sulfide-producing organisms have been found in marine habitats only. Considering the large amount of iron concentrated in magnetosomes (10^{-15} to 10^{-13} g Fe per cell) and the estimated population density of MTB at and below the OAI, MTB are likely to contribute significantly to the flux of reduced Fe to sediments in chemically stratified marine basins.

Magneto-aerotaxis

Magnetotaxis means active motion guided by the magnetic field. MTB passively orient along the geomagnetic field and actively swim by means of flagella. A key element of magnetotaxis is that the cell should possess a large enough magnetic dipole moment to overcome the disorientating effects of thermal motions and be aligned parallel to the magnetic field. In the geomagnetic field, the magnetic energy of magnetotactic cells is typically ten times larger than thermal energy, which means that the cell can migrate along the field at 90% of its forward speed (Frankel et al., 1979).

Magnetotactic Bacteria, Figure 1 A cell of *Magnetospirillum gryphiswaldense* that contains a single chain of magnetite magnetosomes.

“Polar” and “axial” magnetotaxis are distinguished (Frankel et al., 1997). Polar magnetotaxis is displayed by MTB that swim persistently toward one of the poles of a bar magnet under oxic conditions. Those that swim toward the “south” pole of a magnet have North-seeking polarity, since they would swim northward in the geomagnetic field. MTB from the northern hemisphere are predominantly North-seekers, whereas those from the southern hemisphere are predominantly South-seekers (Bazylinski and Frankel, 2004).

The observation of polar magnetotaxis led to the idea that MTB are guided by the geomagnetic field to less oxygenated regions. Since the geomagnetic field is inclined downward from the horizontal in the northern hemisphere and upward in the southern hemisphere under oxic conditions the cells with polar magnetotaxis swim downward in both hemispheres (Bazylinski and Frankel, 2004). However, if the cell is in a reducing environment, it reverses the direction of flagellar rotation and migrates upward. Since the motion of the cell is determined by both the magnetic field and the oxygen tension, the term “magneto-aerotaxis” was introduced (Frankel et al., 1997).

Axial magnetotaxis means that the axis of motion is determined by the magnetic field but its direction is not. As the cell swims, it samples the oxygen concentration and compares it with that in the recent past. Cells moving toward the optimal habitat have a decreased probability of reversing the sense of flagellar rotation, whereas those that are moving away from the optimal oxygen concentration have an increased probability of reversing the sense of flagellar rotation and thus their swimming direction (Frankel et al., 1997). The magneto-aerotactic response provides an

efficient mechanism for MTB to find the OAI in their chemically stratified habitats.

Mineralogy and magnetism

Magnetotaxis relies on intracellular grains of iron oxide or sulfide minerals. Magnetite (Fe_3O_4) is the only iron oxide mineral that has been described to date from magnetotactic cells. The sulfide-producing cells use greigite (Fe_3S_4) for navigation, but they also may contain nonmagnetic mackinawite (FeS) that rapidly converts to greigite through a solid-state phase transition (Pósfai et al., 2007).

Magnetite produced by MTB is chemically pure Fe_3O_4 , in contrast to grains from rocks that usually contain other transition metals besides iron. Structurally, the nanocrystals are either perfect or contain twin boundaries. The morphologies of magnetite magnetosomes are typically highly regulated, strain-specific, and in many cases, unusual for a mineral with cubic symmetry (Pósfai et al., 2007). Whereas magnetotactic spirilla contain cubooctahedral crystals, vibrio and cocci typically produce magnetite with prismatic habits (Figure 2a). Large, rod-shaped cells tend to contain arrowhead- or bullet-shaped magnetite crystals (Bazylinski and Frankel, 2004).

The sizes and shapes of magnetosomes are critical for magnetotaxis. Isolated, isometric magnetite crystals with diameters smaller than ~ 30 nm are superparamagnetic, i.e., they do not have a permanent magnetic moment. Crystals with diameters from ~ 30 to ~ 120 nm are magnetic single domains at room temperature, whereas grains larger than ~ 120 nm contain two or more magnetic domains, reducing the net magnetic moment of the crystal. Most magnetosomes are in the single-domain range, allowing the assembly of a highly efficient internal compass that consists of a chain (or chains) of single-domain magnets. Interactions between neighboring particles in chain configurations ensure that even those magnetite particles that are small enough to be superparamagnetic or large enough to contain two or more magnetic domains if they were isolated are also constrained to be single domains (Dunin-Borkowski et al., 2001). Since elongated particles are arranged with their axis of elongation (which typically coincides with their crystallographic easy magnetization axis) parallel to the chain of magnetosomes, shape anisotropy constrains the magnetic flux lines to be parallel to the axis of motility. Thus, in most magnetite-producing cells the effects of particle size, shape and magnetocrystalline anisotropy, and magnetostatic interactions among particles in chains combine to produce the possible largest magnetic moment (Figure 2b) (Pósfai et al., 2007).

The sizes, shapes, and orientations of iron sulfide magnetosomes are less distinct than those of magnetite magnetosomes. Greigite magnetosomes typically contain planar defects, as a result of an incomplete solid-phase transformation from mackinawite to greigite. The shapes and orientations of the crystals are random,

Magnetotactic Bacteria, Figure 2 (a) Electron micrograph of two double chains of elongated magnetite magnetosomes from a freshwater magnetotactic coccus. (b) Magnetic induction map of a similar double chain of magnetite magnetosomes, obtained from electron holograms.

resulting in poorer confinement and greater variability in the directions of the magnetic induction lines in the cells than in magnetite-bearing bacteria. Remarkably, despite the different crystal structures, orientations, and arrangements of ferrimagnetic crystals, the magnetic moments of different cells are fairly constant (Pósfai et al., 2007), thereby satisfying the requirement for magnetotaxis.

Cell biology and genomic analyses

Magnetic enrichments have shown great morphological and ultrastructural diversity of MTB from a wide variety of aquatic environments. Magnetite-producing morphotypes include spirilla, cocci, vibrios, and rods of various sizes, moving at speeds ranging from 40 to 1,000 $\mu\text{m/s}$. A unique, greigite-producing magnetotactic organism, the “multicellular magnetotactic prokaryote” (MMP) consists of 15–45 cells organized around an internal acellular compartment (Keim et al., 2004). The aggregated cells of the MMP move together as one unit, with the coordinated motion of flagella on the outside of the cells.

The highly controlled, strain-specific properties of magnetite magnetosomes and their chains indicate that biomineralization is under genetic control, executed by specific proteins in the magnetosome membrane. Many details of magnetosome formation have been elucidated by studies of the biochemistry of the magnetosome membrane and genomic analyses of MTB. Workable genetic systems have been developed for two *Magnetospirillum* strains: *M. magnetotacticum* AMB-1 and *M. gryphiswaldense* MSR-1 (Jogler and Schüller, 2007). By genetic manipulation, including the generation of mutants and the expression of magnetobacterial genes in other hosts, the major steps of magnetite biomineralization have been identified in these systems. Magnetite nucleation is preceded by the formation of vesicles, which are invaginations of the cytoplasmic membrane (Komeili et al., 2006). Dissolved ferrous or ferric iron is transported into the cell by an unknown uptake

system. Magnetosome membrane proteins (MamB/MamM) are involved in the transport of ferrous iron from the cytoplasm into the magnetosome vesicle, and then magnetite formation is activated by another protein (MamA). Within the vesicle, iron is oxidized and magnetite nucleation is triggered by the Mms6 protein. The least known aspect of the biomineralization process is the control over the distinct crystal morphology. The vesicles containing fully developed magnetite crystals are anchored to a filamentous cytoskeletal structure by the MamJ protein, resulting in an ordered magnetosome chain (Scheffell et al., 2006). Genomic analyses revealed that the genes that encode the magnetosome proteins are clustered in a 130 kb region, representing a “magnetosome island.” This genomic island appears to be conserved among different *Magnetospirillum* strains and, to a lesser degree, in a magnetotactic coccus (Jogler and Schüller, 2007), raising the question of whether the “magnetosome island” is a universal feature of MTB.

Diversity

The term “magnetotactic bacteria” does not refer to a taxonomical unit. All known MTB belong to various groups within the domain Bacteria. Most magnetotactic microorganisms that are available in pure culture are affiliated with the *Alphaproteobacteria*, including *M. magnetotacticum* and *M. gryphiswaldense*, a marine vibrio (MV-1), and a coccus (MC-1). In addition to the cultivated strains, 16S rRNA analysis of magnetic enrichments from many freshwater and marine samples revealed that a variety of magnetite-producing morphotypes are likely affiliated with the *Alphaproteobacteria* (Amann et al., 2007). Two magnetite-producing candidate species, “*Magnetobacterium bavaricum*” and “*Magnetotacticum bremense*,” are affiliated with the *Nitrospira* phylum.

Sulfide-producing MTB could not have been cultured to date, but a multicellular organism was found to be closely related to the dissimilatory sulfate-reducing

bacteria within the *Deltaproteobacteria*. Another sulfide-producing MTB was assigned to *Gammaproteobacteria*. These findings may suggest that magnetotaxis based on iron oxide and sulfide nanoparticles evolved independently; however, a magnetite-producing, sulfate-reducing organism (*Desulfovibrio magneticus* strain RS-1) is also affiliated with the *Deltaproteobacteria* (Amann et al., 2007).

The diversity of MTB indicates that magnetotaxis evolved independently in several phylogenetic groups. On the other hand, the discovery of a potentially mobil “magnetosome island” in the genome of magnetite-producing MTB could suggest that the trait of magnetotaxis was spread by lateral gene transfer among the various groups of MTB.

Magnetofossils, paleomagnetism

After MTB die, their intracellular magnetite or greigite particles are deposited in the sediment. If diagenetic conditions are favorable, the magnetosome crystals can be preserved as magnetofossils. Magnetofossils have been identified on the basis of the special properties of magnetosome crystals, including a narrow crystal size distribution, characteristic morphologies, chemical purity and, in some cases, chain configurations. Ferrimagnetic nanocrystals presumably originating from MTB have been described from a variety of sedimentary rock types, including clays, carbonates, marls, and evaporites. The magnetofossil record extends from present-day marine and lake sediments to the Cretaceous and with lesser certainty to the late Archean (Kopp and Kirschvink, 2008).

MTB carry a primary remanent magnetization, since they are aligned with the geomagnetic field, presumably even after cell death and burial in the sediment. Because magnetofossils are single magnetic domains, they have an optimized magnetic stability and can be important carriers of paleomagnetic information. Magnetofossils can serve as environmental proxies because MTB live under specific redox conditions. They can also be markers of ancient life, albeit dubious ones, as illustrated by a lengthy debate over whether nanocrystalline magnetite particles in the Martian meteorite ALH84001 represent magnetofossils or had formed inorganically (Winklhofer and Petersen, 2007).

Nanotechnological applications

Magnetic nanoparticles are widely used in technological applications, such as in spintronics, in magnetic inks, in high-density magnetic memory devices, and in medical applications (as contrast agents in magnetic resonance imaging and as magnetic carriers for drug targeting and delivery). Magnetite crystals produced by MTB have uniform sizes and shapes and can be separated from disrupted cells by magnetic methods with their magnetosome membrane intact. The membrane-bound bacterial nanoparticles have a large specific surface area and are well dispersed in aqueous solutions. Antibodies or proteins can be immobilized on the magnetosome membrane, producing

functionalized magnetic nanoparticles (Matsunaga and Arakaki, 2007). Since bound and free analytes can be separated in a magnetic field, bacterial nanoparticles have been used for the rapid and sensitive detection of small molecules, including environmental pollutants, hormones, and toxic detergents. Immunomagnetic particles are also useful for sorting target cells from cell suspensions using a permanent magnet, and for using them in high-performance DNA/mRNA recovery and DNA discrimination analysis (Matsunaga and Arakaki, 2007).

Summary

MTB provide a fascinating example of microbial biomineralization and motivate interdisciplinary research at the junctions of biology, mineralogy, geology, geochemistry, and physics. The molecular and genetic bases of magnetic nanocrystal formation by MTB are now beginning to be understood. The results of research on MTB will be useful for understanding biomineralization processes and magnetic sensing mechanisms in more complex organisms, and for designing nanotechnological applications of bacterial nanocrystals.

MANGANESE (SEDIMENTARY CARBONATES AND SULFIDES)

Michael E. Böttcher
 Leibniz Institute for Baltic Sea Research, Warnemünde,
 Germany

Synonyms

Alabandite; Authigenic manganese minerals; Inca rose; Rambergite; Rhodochrosite

Definition

Rhodochrosite. Manganese(II) carbonate (MnCO_3 ; trigonal, calcite structure), named after the greek word for “rose-colored.” It was named as the state mineral of Colorado (USA) in 2002. Complete solid solution formation with calcite occurs at low temperatures (Böttcher, 1998), the “Ca-rhodochrosites” or “pseudo-kutnahorites” (Mucci, 2004).

Kutnahorite. Manganese(II)-calcium carbonate ($\text{CaMn}(\text{CO}_3)_2$; trigonal; ordered dolomite structure), named after the location KutnoHora (Peacor et al., 1987). Although physicochemically stable at low temperatures

with respect to equally composed solid-solutions (Mucci, 2004), it is not formed in sediments, and only known from high-temperature hydrothermal and metamorphic environments.

Rambergite. Manganese(II) sulfide ($\mu\text{-MnS}$; hexagonal), named after the mineralogist Hans Ramberg, is found as authigenic product in anoxic sediments of the Baltic Sea (Böttcher and Huckriede, 1997; Burke and Kemp, 2002).

Alabandite. Manganese(II) sulfide ($\alpha\text{-MnS}$, cubic), named after the location Alabanda, Turkey, is found in sediments as minor intergrowth with rambergite (Lepland and Stevens, 1998).

Manganese carbonate formation in suboxic/anoxic sediments

Mixed manganese–calcium carbonates, with minor incorporation of magnesium and divalent iron, are formed in (brackish-marine) sediments as authigenic products of suboxic and anoxic early diagenesis, in the Baltic Sea deeps and the Panama Basin. Significant sedimentary Ca-rhodochrosite accumulation requires manganese(IV) dioxide pre-enrichment at the sediment–water interface by episodic water column oxidation, as shown for the temporarily euxinic deeps of the Baltic Sea (Huckriede and Meischner, 1996). The required dissolved carbonate species are formed in the pore water upon mineralization of organic matter, and aqueous Mn^{2+} is derived from microbial or chemical reduction of manganese(III, IV) oxides as electron acceptors (e.g., Banfield and Nealson, 1997). The carbonates occur as kidney-shaped globules, as overgrowth on foraminifers, detrital carbonates, and microbial cells or as idiomorphic crystals, depending on the micro-environment. Experimental studies reveal that the composition of manganese-rich carbonates is controlled by the pore water composition, the abundance of carbonate surfaces, and the presence of inhibitors (Böttcher, 1998; Mucci, 2004). Under equilibrium conditions, natural anoxic pore waters are in the stability field of coexisting rhodochrosite and iron sulfides (Figure 1), and no manganese sulfide should be formed during typically zoned early diagenetic processes.

Manganese sulfide formation in anoxic sediments

The only places worldwide where sedimentary manganese sulfides have been found so far are the Baltic Sea anoxic deeps (e.g., Baron and Debyser, 1957). Idiomorphic MnS (Figure 2) is associated with organic matter, Ca-rhodochrosite, and iron sulfides (Böttcher and Huckriede, 1997; Lepland and Stevens, 1998). Although MnS has been obviously formed under slow diffusion-controlled conditions where rhodochrosite formation was chemically inhibited, the exact process is still under debate. Occurrence of Ca-rhodochrosite replacing hexagonal MnS (Burke and Kemp, 2002) indicates possible readaptation of the metastable sedimentary system toward equilibrium conditions.

Conclusion

Sedimentary authigenic manganese(II) carbonate minerals, especially investigated in the nowadays brackish-marine

Baltic Sea, are indicative of biogeochemical early-diagenetic processes in manganese-rich environments. They have gained a lot of attention in the past 2 decades because of their proxy potential for specific hydrological conditions leading to euxinic water column turnover or glacial-interglacial cycles that are controlled by climate change (e.g., Lepland and Stevens, 1998; Gingele and Kasten, 1994). One of the many open questions within the biogeochemistry and geomicrobiology of manganese in sediments is about the conditions leading to the metastable formation and preservation of manganese(II) sulfides. An interpretation of water profiles in sediments with high manganese load point toward complex interactions between chemical inhibitors, microbial processes, and rates of (temporary) mineral formation processes.

MASS EXTINCTIONS, PHANEROZOIC

Joachim Reitner
University of Göttingen, Göttingen, Germany

Synonyms

Biotic crisis; Extinction event; Extinction-level event

Definition

A *mass extinction* is a sharp decrease in biodiversity, speciation, and diversification rate among micro- and macro-organisms in the fossil record, often also related with a decrease of biomass. The microbial biodiversity, which probably dominates the entire biodiversity, however, is not to be considered under this aspect, because we have no idea about the real microbial biodiversity through time.

Mass extinctions

Mass extinctions are generally important events, which have a large impact on evolutionary processes throughout earth's history. Mass extinctions might have also occurred in the Precambrian, however, these are much more difficult to recognize and interpret, because most of them affected microbial communities. Profound extinction events in the Precambrian are related with the Great Oxidation Event 2.5 Gy ago, during which an unknown number of anaerobic microbial communities disappeared from oxygenated shelf areas and were restricted to the still anaerobic deeper parts of the oceans (Canfield Ocean, see Wiese and Reitner, Chapter *Critical Intervals in Earth History*, this volume). It can be suspected that the Neoproterozoic Cryogenian Snowball Earth situations (730–630 My) damaged early earth's ecosystems as decreasing $\delta^{13}\text{C}$ values prior to the glaciations suggest a decrease in bioproductivity (e.g., Moczyłowska, 2008; Le Guerroué, et al., 2006a, b; Hoffman, this volume). A first macrofossil extinction of eukaryotic multicellular organisms occurred in the Lower Cambrian, when the Ediacara organisms or Vendobionta, respectively (Raup and Sepkoski, 1982; Brasier et al., 1989; Jensen et al., 1998), became extinct.

Within the Phanerozoic, five major mass extinctions are known (Sepkoski, 1984, 1994; Alroy, 2004; Kiessling and Simpson, 2010), in the literature referred to as “the Big Five” (Figure. 1). All of them have potentially different origins (e.g., impact, volcanisms, glaciations a.o.; see below) or are even multicausal. However, in most cases, the triggering mechanisms and feedback loops are often difficult to understand. Apart from cosmic impacts, mass extinctions are most likely no sudden events but have precursory ecosystem perturbations that prelude the phase of the biotic crisis (further reading see Wiese and Reitner, this volume).

End-Ordovician mass extinction (ca. 443 My)

The end-Ordovician mass extinction event is the first major extinction event in the Phanerozoic. Brachiopods, bryozoans, trilobites, graptolites, corals, mollusks, conodonts, etc. were strongly decimated. It is estimated that roughly 50% of known taxa died out (further reading Krug and Patzkowsky, 2004; Sheehan, 2001; Sole and Newman, 2002; Webby and Droser, 2004).

Possible origins

- One reason might be the paleogeographic constellation of the continents at the Ordovician–Silurian boundary, when Gondwana was positioned at the South Pole. The position of large continental areas at the South Pole triggered a severe cooling, which terminated in the Sahara glaciation in the uppermost Ordovician (Hirnantian). Possibly, it was the heaviest glaciation during the entire Phanerozoic. The associated strong regression and a breakdown of oceanic circulation patterns brought up nutrients from the abyssal waters and affected the diversity of organisms negatively (Sheehan, 2001). A further idea is that the glaciation forced an equatorward migration of warmer water organisms, competition in remaining habitats and extinction of a large number of taxa. In a second step, a severe warming, succeeding the Sahara glaciation, forced a poleward migration of the few remaining cold water assemblages, which then also suffered heavy losses (see also Webby and Droser, 2004).
- Melott et al. (2004) argued that the end-Ordovician mass extinction could have been caused by a gamma ray burst from a supernova 6,000 light years distant from the Earth. This burst should have destroyed half of the ozone layer, leading to an immediate kill by the heavy UV radiation. However, any hard data that confirm this model do not exist. As the ozone layer buffers the mutagen UV radiation, an increase of UV radiation should in some kind be visible in the fossil record by an increase of pathologically developed invertebrate macrofossils.
- Young et al. (2009) speculated that CO_2 might play a major role in the end-Ordovician mass extinction. Their idea is that through the late Ordovician massive volcanic CO_2 outgassing was balanced by strong weathering of the uplifting Appalachian Mountains, which sequestered CO_2 . Finally, in the end of the Ordovician, the volcanic activity finished and the continued weathering caused a significant decrease of CO_2 . As a result, the Hirnantian ice age started.

Late Devonian extinction events (ca. 370 My)

Within the late Devonian, several extinction events severely affected biodiversity. The most important ones were the Upper Devonian Kellwasser events in the Frasnian–Famennian boundary interval and the Hangenberg event at the Devonian–Carboniferous boundary (McGhee, 1996; Walliser, 1995; Sandberg et al., 2002). The

Mass Extinctions, Phanerozoic, Figure 1 Compilation of the Big Five Phanerozoic extinction events with the assumed percentage of extinction of known genera. These numbers are highly speculative, because the biodiversity of deep water environments during the extinction events are only poorly known (Figure modified after Sepkoski, 1984, 1994; Alroy, 2004).

extinction seems to have only affected marine life. Reef-building organisms were almost completely wiped out, except some microbial reefs with occasionally few sponges. Roughly 60% of the known genera became extinct. The diversity of brachiopods, cephalopods, trilobites, benthic foraminifera, conodonts, rugose and tabulate corals, jawless fish, stromatoporoid sponges, etc. was strongly influenced by these events. However, the decline of biodiversity is probably a reduction in the formation of new species rather than an extinction of already existing taxa.

Possible origins

Different possibilities have been discussed for the late Devonian mass extinctions such as asteroid impacts, global anoxia, sea-level changes, climatic changes, etc. (Buggisch, 1991; Joachimski, 1997; Joachimski and Buggisch, 1993; Joachimski, 2001). The most intriguing hypothesis is the “Devonian Plant Hypothesis” (Algeo and Scheckler, 1998; Algeo et al., 1995, 2001). Due to the rapid and accelerating evolution of terrestrial plants from the Lower Devonian on, intensified chemical and physical weathering by roots and the increased continental bioturbation resulted in an intensification of pedogenesis. As a result, several feedback loops established. On the

one hand, the increased runoff of nutrients caused eutrophication of the Devonian seas, the genesis of anoxia and black shales, and the extinction of deep water and shelf biota. On the other hand, due to silicate weathering and CO_2 withdrawal from the atmosphere, the alkalinity of the sea increased, enhancing precipitation of carbonates and further CO_2 withdrawal. As a result, a global cooling occurred, and the associated sea-level fall diminished shelf habitat significantly during the Kellwasser and Hangenberg events (e.g., Sandberg et al., 2002).

End-Permian mass extinction (ca. 251.4 My)

The Permian–Triassic extinction was the most severe extinction event within the Phanerozoic. Up to 84% of the known Permian taxa (genera) became extinct. Not only marine organisms were affected, but also terrestrial ecosystems. Many of the characteristic Paleozoic organisms like trilobites, representatives of the cephalopoda and corals, marine and terrestrial vertebrates, and also plants disappeared and died out. However, some of the Permian-style organisms like coralline sponges occurred again in the early–middle Triassic and are interpreted as Lazarus-taxa, a widely, only poorly understood phenomenon. The end-Permian extinction cannot be explained by one event only. The combination of various events is

possibly responsible for this tremendous mass extinction (Benton, 2005; Bowring et al., 1998).

Possible origins

- a. Volcanic events are widely discussed to be the major controlling factor of the Permian–Triassic mass extinction. The most important volcanic events were flood basalt eruptions, which produced the Siberian Traps, some of the largest known volcanic provinces in earth's history. These eruptions have an age of 251.2 ± 0.3 My, and they fit stratigraphically very well with the estimated age of the mass extinction. The Siberian Traps were estimated to exhibit 20% of pyroclastic material, which heavily reduced insolation by backscatter of sunlight. Furthermore, eruptions caused dust clouds, acidic aerosols, and acidic rain, which – in conjunction with the first – disturbed and disrupted photosynthesis on land and in the sea. The Siberian Trap lava intruded into calcareous sediments and large coal beds, and emitted large amounts of CO_2 , causing a slight global warming (White, 2002; Saunders and Reichow, 2009; Reichow et al., 2009).
- b. There is a worldwide negative excursion of $\delta^{13}\text{C}_{\text{carb}}$ to values of ca. -10‰ . There are various possibilities to explain this excursion. However, the release of huge amounts of methane possibly from collapsing marine and permafrost methane hydrates is the most probable reason (Palfy et al., 2001; Twitchett et al., 2001; Payne et al., 2004).
- c. Several pieces of evidence can be brought forward for an impact event in the end of the Permian. There are possible impact craters, which have been proposed as possible causes of the extinction: the Australian Bedout crater and the Wilkes Land crater of East Antarctica. From these sites, shocked quartz and fullerenes, trapping extraterrestrial noble gases, are known. However, this evidence does not really prove the impact event, and the Wilkes Land crater is possibly younger than the Permian–Triassic boundary (Retallack et al., 1998; Becker et al., 2001, 2004). In this respect, the paper by Stanton (2002) is very intriguing, in which he suggests that the Gulf of Mexico is a very huge meteorite crater of end-Permian age – big enough to explain this fatal extinction event.
- d. There is evidence of anoxic seawater conditions around the time of end-Permian extinctions. Major players in anoxic seawater are sulfate-reducing bacteria, which could produce high amounts of H_2S , which is, however, partly re-mineralized in iron sulfides (e.g., pyrite). Dissolved H_2S is a poison and could be responsible for aquatic mass killing. Perhaps, the release of H_2S in to the atmosphere weakened the ozone layer and increased the UV radiation with fatal effects for plants and land animals. There are indications that anaerobic photosynthesis via green sulfur bacteria occurred in the end of the Permian till the early Triassic (Kump et al., 2005; Grice et al., 2005). The triggering mechanism is believed to be the increase of

volcanogenic CO_2 , which lowered the pH value and increased chemical weathering. As a result, the continental runoff of nutrients increased dramatically, causing eutrophication and finally anoxia with the consequences listed above.

- e. Last but not least, sea-level changes are also discussed to explain the mass extinction. Due to the Pangea situation, a very big marine regression is noticed. This reduced the shelfal areas, biodiversity, and the stability of food chains (e.g., Hallam and Wignall, 1999).

End-Triassic mass extinction (ca. 201.4 My)

The end-Triassic extinction defines the boundary between the Triassic and Jurassic, and it is one of the most important Phanerozoic extinction events. Ca. 47% of the known genera got extinct, such as the conodonts, nearly almost all Triassic taxa of ammonites except the stem groups of the Phylloceratina and the Lytoceratina. Many vertebrates such as a high number of large amphibians, Triassic archosaurs, many therapsids, etc. disappeared. The end-Triassic extinction event also destroyed the widespread shallow water coral reef environments, including many types of corals and especially coralline sponges. The recovery of this coral reef environment took a long time and was more or less completed in the Upper Jurassic (Hallam, 1987, 1997; Palfy et al., 2001; Ward et al., 2001).

Possible origins

There is only one seriously discussed reason for the end-Triassic extinction. During this time, a tremendous volcanic activity occurred, the Central Atlantic Magmatic Province (CAMP), which produced huge amounts of flood basalts, linked with a high amount of outgassing CO_2 , sulfur gases, and volcanic ash (Hesselbo et al., 2002). This event heavily influenced the shallow water and terrestrial bioproduction and, probably due to acid rains, also biomineralization. The $\delta^{13}\text{C}$ isotopic composition of organic matter from sediments from this time exhibits an unusual negative excursion (Deenen et al., 2010; Ruhl et al., 2009; Whiteside et al., 2010). Most probable trigger for the extinction is the CAMP-induced climatic change, acidification of the ocean surface waters, and a strong sea-level fall.

End-Cretaceous mass extinction (ca. 65.5 My)

The end-Cretaceous extinction event, also known as the Kreide–Tertiary (K-T) extinction event, was a very short-termed mass extinction event. However, the diversity of some groups of animals like ammonites, belemnites, various Cretaceous bivalves (rudists, inoceramids), dinosaurs, etc. decreased before the K-T event. The most important impact on biodiversity was the extinction of non-feathered dinosaurs, marine large reptiles (mosasaurs, plesiosaurs), pterosaurs, and the decrease of phyto- and zooplankton diversity and biomass in the ocean surface waters. Crocodilian archosaurs, turtles, birds, and small nocturnal mammalian survived the mass extinction event.

Extinction of most taxa of, for example, coccolithophorids and Cretaceous planktonic foraminifera led to a breakdown of primary productivity and calcareous sedimentation rates in the oceans. The K-T boundary layer is worldwide often documented as a black band, which exhibits geochemical anomalies, for example, an enrichment of iridium and in the Pt-group elements in general. Probably, ca. 47% of the known genera became extinct.

Possible origins

- a. The most discussed reason is that huge impacts of cometary parts or asteroids caused the extinction. This assumption is evidenced by the geochemical anomalies (Ir, Pt-group) and the discovery of a very large impact structure in northern Mexico (Yucatan), the Chicxulub crater, which has an age corresponding to that of the K-T boundary. Some scientists assume that more impacts happened; however, no further impact structures are known. The ecological disaster shortly after the huge meteorite impact (estimated size of impactor more than 10 km) caused the extinction of the above-listed organisms.
- b. Beside the bolide impact hypothesis, an increased volcanic activity is also discussed to be responsible for the big extinction event. The Deccan trap basalts have the age of the K-T boundary, and this vast volcanic event might also have influenced the biodiversity and biomass production at that time, which then reflects a comparable scenario like for the Permian-Triassic boundary. It is easily possible that the conjunction of two events – the bolide impact and the Deccan trap volcanism – are responsible for this last large Phanerozoic mega extinction.

Conclusion

All five major extinction events within Phanerozoic are milestones in the evolution of organisms, community structures, and ecosystems. All of them are critical intervals (see contribution Wiese and Reitner this volume) and of fundamental paleobiological importance. All of the major extinction events are multicausal events and cannot be restricted to only one factor. Most of them are also not short-term events, except the K-T boundary event which is proved to be a large meteorite impact. However, also in this case, the extinction of some important taxa has a prelude in the form of successive decrease in diversity, and the K-T event finally wiped them out.

These catastrophic events are probably very important for the entire biotic evolution on earth and obviously one of major evolutionary driving force.

MAT-RELATED SEDIMENTARY STRUCTURES

Hubertus Porada
 University of Göttingen, Göttingen, Germany

Synonyms

Microbially induced sedimentary structures (MISS) (The acronym MISS was introduced by Noffke et al. (2001) for “microbially induced sedimentary structures.” Many of the structures addressed, however, are not truly “induced” by microbes, but rather by physical forces

acting on a biostabilized sediment surface or a microbial mat. Since, in this scenario, the biological component significantly influences the shape of evolving structures, it is suggested to write out the acronym MISS as “microbially influenced sedimentary structures.”).

Definition

Mat-related sedimentary structures are small- to medium-scale sedimentary structures resulting from growth and extension of microbial populations and communities on a sediment surface, stabilization of surface sediments, trapping and binding of sediment particles, and from the impact of environmental factors, such as inundation, sedimentary deposition, subaerial desiccation, wind- or current-induced traction, on epibenthic microbial mats.

Introduction

Originally described from and applied to modern microbial mats (Gerdes et al., 2000; Noffke et al., 2001), mat-related sedimentary structures preferentially serve as proxies of the former existence of microbial mats in ancient siliciclastic sediments. Mat-related structures are in a way analogous to trace fossils (Schieber, 2004), whereby the former presence of mats can be inferred, e.g., from observations suggesting “unusual” sediment properties like original cohesiveness, tensile strength, and erosion-resistance of sand (Eriksson et al., 2007); uncharacteristic grain fabrics; and steep geochemical gradients on a mm-scale. Genetic explanation of the structures relies on an actualistic approach; preservation depends on intrinsic biological, and favorable environmental conditions.

In this chapter, the term “mat-related sedimentary structures” is applied to structures that form on, in, or below microbial mats with distinct properties, e.g., coherence, cohesiveness, minor thickness, and adaptation to periodic subaerial exposure. Further conditions include a fine-grained siliciclastic substrate (sand to silt) and lacking dominance of carbonate precipitation. The term also encompasses primary physical structures that have subsequently been microbially influenced.

Today, well-developed (cyanobacterial) microbial mats that meet the above conditions, are observed mainly in the intertidal to lower supratidal zones of low-gradient tidal flats where they grow in a wide range of climate zones from temperate humid to subtropical/tropical semi-arid and arid, at salinities ranging from brackish to hypersaline. Similar mats may also form in other environments, e.g., lacustrine, fluvial, where similar mat-related structures may partly form. Due to lacking vertical bioturbation in the Precambrian, the distribution of microbial mats may previously have been much wider, extending far into the subtidal zone.

Microbial mats are epibenthic, multilayered microbial communities including different functional groups of microorganisms (Stal, 2000) which act together in a kind of “joint venture” widely balancing organic matter production and destruction (van Gernerden, 1993). Thus, microbial mats in coastal environments normally do not

exceed a thickness of a few centimeters. The “biological stratification” of microorganisms is superimposed by a biosedimentary lamination resulting from the interplay of microbial growth and seasonal, periodic, or episodic depositional events related, e.g., to tides or storms.

The top layer of the mat system, which periodically is exposed to the atmosphere, usually consists of oxygenic, filamentous cyanobacteria, frequently *Microcoleus* sp., which form a “felty” fabric of interwoven filaments (Gerdes et al., 2000), including also sediment grains incorporated by “trapping and binding” processes (Noffke et al., 2003a, with references). The felty layer may be overlain, or in some cases replaced, by a resistant (“leathery”) layer of colloid extracellular polymeric substances (EPS) produced mainly by coccoid cyanobacteria. This top portion of the mat combines high mechanical resistance with low permeability and is the locus at which most of the mat-related sedimentary structures form. Deeper levels of the mat system are much less cohesive. They contain anaerobic bacteria among which sulfate-reducing bacteria produce sulfide leading to precipitation of iron sulfides (FeS) which gradually transform into pyrite. In the ancient record, the stratiform occurrence of pyrite, in some cases siderite or ferroan carbonate, within otherwise well oxidized sediments may serve as a proxy of the former existence of microbial mats.

Formation and types of structures

Mat-related sedimentary structures may form during all the stages from first microbial colonization of a sediment surface, through establishment and sustainment of a fully developed mat, to its destruction and final erosion.

Structures related to early microbial colonization

Microbial colonization leads to “biostabilization” (Krumbein et al., 1994) of a sediment surface which then can resist erosion to some degree. This property may lead to “palimpsest ripples” when new sediment is deposited on top a biostabilized rippled surface (Pflüger, 1999); to surfaces with “multi-directional ripple marks” (Noffke, 1998); and to “ripple patches” (Figure 1a) or “erosional pockets” when a biostabilized flat surface or mat is locally eroded (for ancient example, Noffke, 1999; McKenzie, 1972).

Structures related to microbial growth and mat growth

Depending on availability of water for some time, specific filamentous cyanobacteria (e.g., *Lyngbya aestuarii*) start to produce on the mat surface, a characteristic “reticulate growth pattern” of small, sharp-crested ridges stabilized by EPS (Figure 1b). Ancient structures of this type are named “elephant skin” texture (Gehling, 1999) (Figure 1c). There is considerable variability in respect of polygon size (few mm to few cm) and shape varying from nearly circular to narrow rectangular with almost linear crest orientation. A unifying feature, however, are the

(e) Modern and ancient shrinkage cracks. *Left photograph*: modern microbial mat with isolated, sigmoidal, and tri-radiate cracks. Locality: Amrum Island, southern North Sea, Germany. *Right photograph*: fillings of ancient, spindle-shaped, and tri-radiate cracks. Locality: Neoproterozoic Tizi n-Taghatine Group; Imi n'Tizi area, Anti-Atlas, Morocco. (f) *Manchuriophycus*-type shrinkage cracks meandering in ripple troughs. Locality: Neoproterozoic Tizi n-Taghatine Group; Taghdout area, Anti-Atlas, Morocco.

narrow, sharp-crested ridges preserved on upper bedding surfaces.

A further type of structures related to mat growth are “mat expansion structures,” collectively termed “petees” (Gavish et al., 1985; Bouougri et al., 2007), which deform the upper, cohesive part of the mat into bulges and domes, thus enlarging the mat surface (Figure 1d). Occasionally, the bulges may be arranged in a polygonal pattern. Provided, petees are filled by sediment rising up from below, the structures may be preserved. Ancient examples have been named “petee ridges” (Schieber, 2004).

Structures related to mat desiccation and shrinkage
Subaerial exposure causes dehydration and shrinkage of the EPS and eventually cracking of the mat. Incipient,

isolated “shrinkage cracks” are sigmoidal and spindle-shaped, or tri-radiate starting from triple junctions, or occasionally circular in shape (Figure 1e). Crack propagation at progressive shrinkage leads to more or less complete networks of cracks. In general, shrinkage cracks in microbial mats develop a higher degree of curving unlike normal mud cracks. Ancient shrinkage cracks are also termed “sand cracks” referring to their occurrence in sandy sediment without shrinkable mud present. A specific type of shrinkage cracks, characterized by sinuoidal or sub-circular trends and developed mainly in ripple troughs, is referred to as “*Manchuriophycus*”-type in the ancient record (Porada and Löffler, 2000) (Figure 1f). A characteristic property of many ancient shrinkage cracks is their easy separability from the layers above and below, which is ascribed to soon microbial

Mat-Related Sedimentary Structures, Figure 2 Structures related to mat desiccation and deformation. (a) Polygonal pattern of shrinkage cracks with upturned margins in thick microbial mat. Scale (knife) is 8 cm. Locality: Trucial Coast, west of Abu Dhabi, U.A.E. (b) Surface outcrop of Holocene microbial mat exhibiting relics of polygons with upturned margins. Scale (knife) is 8 cm. Locality: Trucial Coast, west of Abu Dhabi, U.A.E. (c) Irregular to subcircular openings with curled margins, formed in a thin microbial mat due to desiccation and shrinkage. Note newly overgrown margin in lower right of photograph. Locality: Sabkha El Gourine, Mediterranean coast of southern Tunisia. (d) Upper surface of siltstone layer exhibiting irregular to circular cracks. The structures are interpreted as openings in a previous thin mat that underwent desiccation. Locality: Terminal Proterozoic Vingerbreek Member, Nama Group; Farm Haruchas, Namibia. (e) Microbial mat, torn and partly removed by current or wind action. Flip-overs of mat margins are indicated by "F." Note small-scale desiccation cracks in exposed mat substratum. Locality: Sabkhet Mjasser, Mediterranean coast of southern Tunisia. (f) "Roll-up" structure ("jelly-roll") consisting of rolled-up microbial mat and adhering sediment. Scale (coin) is 23 mm. Locality: Bhar Alouane, Mediterranean coast of southern Tunisia.

overgrowth of the crack margins and of the sediment trapped in the crack.

Thick mats, frequently dominated by *Microcoleus chthonoplastes*, tend to form polygonal networks of wide cracks with "upturned" or involute, "curled margins" (Figure 2a); individual polygons may range in size from 10 to 60 cm across, depending likely on the thickness of the mat. Ancient examples exhibit a "chaotic" upper surface with irregularly oriented bedding (Figure 2b) and resemble sedimentary structures ascribed to seismic events (Donaldson and Chiarenzelli, 2007).

Thin mats, frequently dominated by coccoid cyanobacteria and vested with a strong EPS top layer, tend

to form circular openings with curled margins around (Figure 2c). Ancient examples have been described from thin siltstone layers within heterolithic deposits (Bouougri and Porada, 2007) (Figure 2d).

Structures related to mat deformation, destruction, and erosion

Cohesive microbial mats may become torn, detached from the substratum and tightly folded, and eventually eroded by strong currents, e.g., during storm and flooding events. Mats are also destroyed by complete desiccation after cessation of groundwater supply, and dried mat fragments

may be transported by wind over wide distances and be deposited in environments where mats usually do not grow.

Mat destruction by currents leads to typical structures repeatedly observed in modern environments and in the ancient record: (1) “flip-over” structures (Figure 2e) result when a mat’s edge is flipped over; (2) cigar-shaped “roll-up” structures, also named roll-ups or “jelly-rolls” (Figure 2f), may develop when curled margins or flip-overs undergo additional rolling due to current action; and (3) irregular or arcuate belts of “mat deformation folds” form when a torn and detached mat is crumpled by tractional forces (Figure 3a); similar folds may also result from mat slumping on steep slopes, e.g., along tidal channels. Roll-up structures can withstand transport over some distance and may gather along trash lines, whereas

the other structures largely remain in situ. For ancient examples see Schieber et al. (2007).

“Mat chips” (Gerdes et al., 2000) are small fragments of eroded mats or biostabilized sediment. They primarily are irregular in shape with frayed edges, but may become pebble-shaped with transport (Figure 3b). Ancient examples have been named “microbial sand chips” (Pflüger and Gresse, 1996) or “sand clasts” in contrast to intraformational mud clasts (Figure 3c).

Structures formed beneath microbial mats

From the hydraulic perspective, the sediment beneath cohesive and coherent microbial mats may be addressed and treated as a confined aquifer in which, at sufficient hydraulic head, a potential for liquefaction may develop (Porada et al., 2007). In such case, hydraulic upward

Mat-Related Sedimentary Structures, Figure 3 Structures related to mat deformation and erosion, and subsurface structures. Scale (knife) in a, b, e, and f is 8 cm. (a) Detached, thin microbial mat, torn and strongly deformed by current action. Locality: Coastal sabkha between Gabes and Skhirat, Mediterranean coast of southern Tunisia. (b) Modern sandy-pebbly sediment surface with subrounded to rounded “mat chips”. Locality: Salins du Midi, Réserve Nationale Camargue, southern France. (c) Upper surface of sandstone bed carrying subrounded to rounded “sand clasts,” interpreted as previous “mat chips.”. Locality: Terminal Proterozoic Vingerbreek Member, Nama Group; Farm Haruchas, Namibia. (d) Morphological details of a mat subsurface, exposed after removal of the mat. Scale (coin) is 24 mm. Locality: Sabkhet Mjasser, Mediterranean coast of southern Tunisia. (e) Upper surface of sandstone layer exhibiting irregular bulges and domes. The structure is considered to represent morphological features of a previous mat subsurface. Note tri-radiate crack in well-developed dome just below scale. Locality: Neoproterozoic Tizin-Taghatine Group; Taghdout area, Anti-Atlas, Morocco. (f) Upper surface of sandstone layer with “Kinneyia” structure. Locality: Terminal Proterozoic Vingerbreek Member, Nama Group; Farm Haruchas, Namibia.

pressure will lead to slow, upward movement of sediment grains. As a result, bulges and domes developed in the mat will gradually be filled from below; “petee ridges” have been quoted as an example above.

Thin microbial mats, particularly those dominated by coccoid cyanobacteria, may develop very irregular surfaces with numerous small domes and buckles which also appear as positive features on the subsurface (Figure 3d). Ancient examples of such “subsurface structures” strongly resemble load structures but are clearly distinguished from these by their occurrence as positive features on *upper* bedding surfaces (Figure 3e).

“Kinneyia” (Figure 3f) is a further structure developed in the sediment beneath a microbial mat. The structure is characterized by millimeter-scale, flat-topped, steeply sided, winding ridges separated by equally sized round-bottomed troughs and pits. It resembles small-scale interference ripples including crest-dominated linear and pit-dominated honeycomb-like patterns. The structure has been described from the Archean (Noffke et al., 2003b) to the Jurassic (Bloos, 1976), but not yet from the Recent. Genetic interpretation is thus difficult. Recent models suggest formation by trapping of gas underneath a sealing mat (Pflüger, 1999) or by reversals of groundwater flow in the liquefied mat substratum (Porada et al., 2007).

Wrinkle structures

The term “wrinkle structure” (Hagadorn and Bottjer, 1997, 1999) is currently used as a collective term for various small-scale irregularities developed on ancient, siliciclastic sediment surfaces. Application of the term implies that a microbial participation in the formation of the structure is suspected, at the least. Within this broad definition, wrinkle structures may originate from very different processes including microbial growth, mat deformation and subsurface processes (Porada and Bouougri, 2007). Included in the term are also structures like elephant skin and Kinneyia which are well defined and for which, if clearly identified, usage of the proper name is recommended.

Preservation of mat-related structures

As most of the organic matter produced by the cyanobacteria is soon decomposed and mineralized so that organic components or even carbon are rarely preserved in the ancient siliciclastic record, preservation of mat-related structures is largely dependent on the volume of inorganic material bound or produced by the mat or trapped by the structure. Microbially supported processes introducing inorganic material into the mat include “trapping and binding” of silt- to sand-sized grains and possibly clay minerals, formation of authigenic clay minerals during bacterial lysis, formation of iron sulfides and pyrite, and precipitation of carbonates. The mat-related structures themselves, being either positive or negative features on the mat surface, may act as sediments traps. Thus, shrinkage cracks may become filled with sediment by currents or

colian action, and involute (curled) margins may trap grains in their windings.

Another mechanism by which some mat-related structures, e.g., domes and bulges developed in the mat, may become preserved is “filling from below.” This process requires comparatively high hydraulic upward pressure enabling liquefaction of the sediment below the sealing mat so that grains are lifted and moved upwards. As a result, a previously flat surface of a sedimentary layer may be transformed into an irregular surface mimicking morphological features of the mat.

Conclusions

Simplistically subsumed under the main groups of “wrinkles,” “unusual cracks,” and mat chips in the fossil record, mat-related sedimentary structures exhibit a wide range of shapes and patterns resulting from various processes and interactions between conflicting biological and physical factors. Due to local microtopographic features and the intrinsic inhomogeneity of microbial mats on a small scale, even well-defined structures, like elephant skin or Kinneyia, may show a high degree of variability. Thus, one structure almost never is like the other and the paradigm of reproducibility is not strictly applicable to them. Nevertheless, the structures are distinctive as exemplified on Figures 1–3.

Mat-related sedimentary structures may serve as tools for detailed facies analysis in siliciclastic peritidal settings. Based on modern analogs, most of the structures form in the intertidal to supratidal zones, but mat extent may have been wider in the Precambrian. Structures requiring (at least temporarily) subaerial exposure for their formation, e.g., types of shrinkage cracks with or without upturned or curled margins, clearly indicate intertidal to supratidal positions, whereas others remain less unequivocal. Subsurface structures including Kinneyia may form down to the shallow subtidal zone, as long as coherent, cohesive mats are present.

In the fossil record, the significance of mat-related sedimentary structures increases greatly if several types are observed in association. Some mat-related structures, e.g., reticulate growth patterns, preferentially occur in heterolithic successions of thinly laminated siltstone and mudstone which, in some cases, may be addressed as “siliciclastic biolaminites” resulting from the interaction of microbial mat growth and sediment supply (Bouougri and Porada, 2007), whereas sand cracks are usually developed on sandstone layers intercalated in the succession. In contrast, Kinneyia structures exclusively occur on upper surfaces of sandstone beds which frequently represent event deposits after storms or floods.

METAGENOMICS

Wolfgang Liebl
 Technische Universität München,
 Freising-Weihenstephan, Germany

Definition

Metagenomics is a research discipline that uses molecular biology methods to acquire, analyze, and interpret sequence data and/or functional data from the metagenomes (the collectivity of genomes) present in the environmental samples, without the need to cultivate the organisms in the samples. Related methodologies are so-called metatranscriptomics and metaproteomics that focus on the collective transcriptomes and proteomes, respectively, rather than on the genomes.

Introduction

Microorganisms constitute major life forms on earth with respect to cell numbers and total biomass, and fulfill essential functions in global element cycles. It has been estimated that the earth's biosphere harbors at least two to three orders of magnitude more prokaryotic cells ($4\text{--}6 \times 10^{30}$) than the number of plant and animal cells combined. The total carbon fixed in prokaryotic cells amounts to $3.5\text{--}5.5 \times 10^{17}$ g of C which is 60–100% of the estimated total carbon in plants (Whitman et al., 1998).

For many decades since the beginnings of microbiology, research in this field has depended on the isolation and cultivation of individual microorganisms (best illustrated for the area of medical microbiology with the work of Robert Koch on the isolation and characterization of pathogenic bacteria in monocultures, leading to the Koch's postulates) or well-defined syntrophic consortia, and the subsequent in-depth analysis of pure cultures. Until today, microbiological research with traditional cultivation and

subsequent chemical, genetic, and physiological characterization has led to the description of roughly 10^4 bacterial and archaeal species deposited as pure cultures in microbial culture collections. However, in the course of the past 2 decades, it has become more and more evident that the microbial diversity in most aquatic habitats, soil, as well as oceanic and terrestrial subsurfaces is enormous (Amann et al., 1995; Hugenholtz et al., 1998; Quince et al., 2008; Sleator et al., 2008) and that at least at present the majority (>99%) of microorganisms in many complex habitats are not cultivated by using standard techniques (Amann et al., 1995). Thus, it must be acknowledged that the number of described species contrasts by orders of magnitude with estimates about the number of prokaryotic taxa on earth which may amount to 10^6 – 10^8 distinct genospecies (Simon and Daniel, 2010). Metagenomics, a relatively young research discipline, can aid in the detection and acquisition of data about this vast majority of uncultured microorganisms. For this methodology, which importantly is independent of cultivation, the collectivity of genomes (the metagenome) present in a given environmental sample is extracted and subjected to completely random or gene-targeted sequence analysis (Figure 1).

Although bacteria and archaea normally are unicellular, they usually occur as highly diverse but often poorly characterized consortia in their natural habitats. Individual environmental samples can contain a breathtaking prokaryotic diversity. For example, the numbers of different molecular species or operational taxonomic units (OTUs) in soil samples could be over 10^6 (Curtis et al., 2002). Statistics-based predictions for a specific Canadian soil sample range from 2×10^4 to 1.4×10^5 taxa (Quince et al., 2008). Highly interesting, based on taxonomy assessment results from deep-sea hydrothermal vent samples and statistical follow-up considerations, even samples from extreme environments – which often are believed to contain only limited biodiversity due to the extreme conditions – have revealed enormous microbial biodiversity, for example, 3×10^5 bacterial taxa at one specific sample site (Quince et al., 2008). These numbers illustrate the problems one faces to reach near-complete metagenomic datasets for complex natural habitats with today's analysis techniques. Thus, even with high-throughput methods, it is difficult if not impossible to generate a complete microbial inventory of a habitat including also most of the rare taxa. However, the methods available do allow the reliable

Metagenomics, Figure 1 Flowchart summarizing steps of environmental meta-analysis.

identification of the abundant taxa that presumably account for the major biogeochemical conversions.

Uses and applications of metagenome analysis

One major advantage of metagenomic analysis is that one can obtain a wealth of genetic information about organisms that live together in more- or less-complex communities, most of which cannot be cultivated with today's standard techniques. It can be used for extremely diverse purposes, such as the analysis of fundamental aspects of microbial community structure, function, and adaptation in environmental microbiology, but also to explore and exploit the microbial genetic, metabolic, and enzymatic diversity space for the development or improvement of biotechnological processes. Examples for the application of metagenomic techniques in geobiology are the analysis of microbial communities in rock material, sediments, aquifers, as well as in biofilms, on rock surfaces or in subsurface caves and mines, etc. It must be stressed that it is of utmost importance for most metagenomic studies to comprehensively record the sample-associated metadata (the data about the data), like date and position of sampling, physical and chemical characteristics, etc., as has been pointed out by Wooley et al. (2010).

Principally, metagenome analysis can be applied to any kind of habitat, irrespective of the complexity of the microbial communities present. For low-diversity habitats, high-throughput metagenome sequencing can yield a comprehensive overview of genetic information present and can even allow the near-complete or complete assembly of whole prokaryotic genomes, which was nicely shown for the organisms present in acid mine drain fluids (Tyson et al., 2004) or community genome sequencing of an anammox bacterium (Strous et al., 2006). However, the more diverse the community, the higher the sequencing and/or screening effort has to be to arrive at results that cover as comprehensively as possible the target genes of interest present in the sample. In some cases, it is possible to reduce the amount of work and costs by choosing a more specific than a completely random metagenome analysis. For example, if the main interest of a study lies in the analysis of genes involved in a certain metabolic trait (like breakdown and utilization of a specific substrate), one can try to enrich for the corresponding genes by carrying out enrichment cultures wherein the growth of organisms which display this metabolic trait is favored (e.g., by supplying the said specific substrate as the sole carbon source). Enrichment cultivation also has the advantages that (i) more cell material becomes available and that (ii) less organic and inorganic contaminating compounds from the original habitat sample that may interfere with DNA isolation yield and quality are present. An alternative is to enrich for genomic DNA or RNA from microorganisms with a certain substrate utilization capability by feeding a natural microbial community with ^{13}C - or ^{15}N -labeled substrate and then to isolate and process only the heavy nucleic acid that stems from

organisms that utilized the added ^{13}C - or ^{15}N -substrate and incorporated the label into their nucleic acids (stable isotope probing) (Friedrich, 2006; Neufeld et al., 2007). Using enrichment cultures to preselect for microorganisms with certain physiological traits has been successfully done in several cases (e.g., Entcheva et al., 2001) and may be of advantage especially for very complex microbial communities, but it has to be kept in mind that any kind of cultivation step before DNA isolation can result in dramatic changes in community composition and diversity.

Assessment of phylogenetic and functional diversity

Sequence analysis of conserved marker genes, usually 16S rRNA genes, is widely used for community diversity assessment. To this end, 16S rRNA gene sequences can be amplified with PCR directly from metagenomic DNA samples, followed by cloning into appropriate vectors and sequence analysis. Also, the sequences of conserved marker genes (rRNA genes, but also protein-encoding marker genes) can be retrieved from large sequence datasets compiled by large-scale random sequencing of metagenome DNA and then used for phylogenetic community composition assessment (von Mering et al., 2007).

Recently, massively parallel sequencing specifically of rRNA gene fragments amplified from metagenomic DNA has become possible by the use of the 454 Life Sciences (Roche) high-throughput tag pyrosequencing technology (Huse et al., 2008), but due to the fact that read-length limitations presently only allow the sequencing of incomplete rRNA gene fragments, this technology is suited for the trustworthy phylogenetic assignment at the phylum level but is not as reliable at the genus or species level. Nonetheless, this method allows interesting insights into the affiliation of microorganisms from complex communities to the large phylogenetic lineages, and technological improvements pertaining to the read lengths will surely allow more precise analyses at the genus or species level in the near future.

Bioinformatic tools are available for the comprehensive phylogenetic tree calculation from alignments of conserved marker sequences, for example, the ARB software package (Ludwig et al., 2004). Also, other sequence information than merely phylogenetically conserved genes available from large metagenomic random DNA sequence datasets can be used for diversity assessment. In the past years, various software tools have been developed that are useful for the so-called taxonomic binning of such sequence information (see Simon and Daniel, 2010). While some algorithms work on the basis of oligonucleotide sequence frequencies (composition-based binning, e.g., PhyloPhytia, TETRA; Teeling et al., 2004; McHardy et al., 2007), which are known to vary between different genomes, others use comparative orthologous ORF analysis for this purpose (CARMA, MEGAN, Sort-ITEMS; Huson et al., 2007; Krause et al., 2008; Monzoorul et al., 2009). Importantly, however, since most of these

bioinformatic tools depend on genome sequences and annotations from the available reference genome databases, which presently cover only a minority of the (readily) culturable species (not to speak of the enormous uncultured species diversity present in nature [see above]), our present possibilities for the assignment of short metagenomic DNA sequences to microbial taxa are quite limited.

Current large-scale efforts to sequence the genomes of the prokaryotic species deposited in major microbiological culture collections (GEBA, a Genomic Encyclopedia of Bacteria and Archaea; <http://www.jgi.doe.gov/programs/GEBA/>; Wu et al., 2009) will surely dramatically improve the reference genome sequence database necessary for a more accurate phylogenetic assignment of metagenomic sequence fragments. Nevertheless, considering that there are still in some cases not a single, in other cases only very few cultured representatives for some deep-rooting phyla, severe limitations in our ability to reliably assign short metagenomic DNA sequences to phylogenetic taxa will remain at least in the near future.

Screening for genes in metagenomes

Metagenomic studies often include the screening of metagenomic libraries or metagenomic sequence datasets for genes of interest, for example, for genes encoding key enzymes characteristic for habitat-specific physiological traits, or for genes for biotechnologically relevant enzymes. Two fundamentally different approaches are used for this: the sequence-based approach and the function-based approach. Both methods have individual advantages and disadvantages and are explained briefly in the following.

The *sequence-based approach* uses in silico sequence mining, PCR amplification or hybridization methods to detect and isolate genes of interest. Metagenomic sequence datasets can be scored for fragments encoding orthologs of known genes deposited in the available reference databases. Various bioinformatic tools such as BLAST, Pfam, SEED, TIGRFAM, MEX, RAMMCAP, or MG-RAST are available which are helpful for the functional annotation of metagenome sequence data (see Simon and Daniel, 2010; Wooley et al., 2010). Another sequence-driven approach is to design degenerate PCR primers directed against conserved sequence motifs in a gene family of interest and to amplify partial ORFs from metagenomic DNA. The fragments can then be used to isolate the complete ORFs, for example, by using them as hybridization probes to identify clones or metagenomic DNA fragments containing the adjacent, missing ORF sequences, or by metagenome walking (see Simon and Daniel, 2010). Alternatively, DNA microarrays carrying oligonucleotides derived from consensus sequences of known genes have been used for the sequence-directed screening of a metagenomic library for a light, oxygen and voltage (LOV) domain blue light photoreceptor gene (Pathak et al., 2009). The major disadvantage of sequence-based gene detection is that this method depends on prior sequence information from known gene families.

Therefore, truly novel genes unrelated to the already known genes encoding for a given function cannot be identified with this approach.

In the *function-based screening approach*, clones from metagenomic libraries are subjected to activity-based assays that indicate the function of interest. The major advantage of this approach is that it allows the recovery of complete genes or gene clusters and of novel types of enzymes without any prior knowledge of the sequence. However, in order to work efficiently, the genes of interest, which often originated from uncultured microorganisms with unknown genetics and physiology, must be compatible with the expression machinery provided by the heterologous screening host with respect to transcription, translation, protein folding, and eventually secretion (Gabor et al., 2004). Therefore, the fraction of the existing enzymatic diversity that can be accessed via functional screening approaches is strongly influenced by the choice of the host organism used. The phylogenetic distance between the gene donor and the cloning/expression host may be crucial for the success of gene expression. Mostly, *Escherichia coli* is used to construct metagenomic libraries for functional screening, but it is clear that the expression of metagenomic genes can be severely biased in this host. Therefore, it is important to establish and improve an alternative host/vector systems in order to enhance the probability of detecting genes from metagenomic samples (Angelov et al., 2009; Steele et al., 2009; Uchiyama and Miyazaki, 2009).

Some restrictions and problems

Despite the power of metagenomic studies to unravel genetic information from microbes in communities that are not amenable to cultivation and in-depth characterization, a number of restrictions and problems remain, only some of which are listed hereafter.

Huge amounts of data are generated, especially in metagenome random sequencing projects. These data need to be generated, processed, and stored in a complex succession of steps. Special care must be taken with respect to library construction and sequencing quality. Exemplarily, the procedure of a metagenomic sequencing project is described by Kunin et al. (2008). A useful compilation of software tools for composition-based and similarity-based taxonomic binning, functional annotation of metagenomic data, and comparative metagenomics can be found in Wooley et al. (2010).

Interpretation of the sequence data and their connection with biochemical functions of biocatalysts remains a challenging task. The tools for ORF extraction from metagenomic sequence data and bioinformatics-driven function prediction are being improved constantly, but it is of course not feasible to check all gene function predictions experimentally, for example, by heterologous expression and biochemical analysis. Also, if only metagenomic DNA sequence data are available, it is unclear if the genes found are expressed at all. Thus, it has to be kept in mind that in many cases sequence data

obtained from metagenomes only indirectly point to (predicted) enzymes/pathways of the organisms in the sample. In future, performing metatranscriptomics and/or metaproteomics experiments in parallel with metagenomics can help to overcome this problem.

Also, linking phylogenetic and functional metagenomic data with the physiology of living microorganisms in the environmental sample is a crucial but not a trivial step for many studies attempting to correlate environmental data with a microbial community. Due to the species complexity in most microbial communities, it is only rarely possible to obtain assembled genomes. Even if conserved marker sequences point to close relatives of certain well-known microorganisms this does not necessarily prove that the organisms from which the metagenomic sequence information was derived have identical physiologies as the reference organisms. Also, some traits believed to be characteristic for certain phylogenetic groups of microorganisms can get lost by simple mutations. Still, it is possible to extract environment-specific gene fingerprints from unassembled random environmental DNA sequencing data that reflect known characteristics of the sampled environments, thus linking metagenomic sequence information with metabolic functions of the organisms present (Tringe et al., 2005).

Finally, since most conclusions reached from metagenome data analysis rely on comparative sequence analysis and thus are indirect, it will be important to develop and improve new microbiological cultivation and characterization techniques that also allow the cultivation and in vivo analysis of physiologically and quantitatively dominant microbial representatives within the studied communities.

Summary

Considering the enormous microbial diversity in most environmental samples on one hand and the current shortcoming of the microbiologists' ability to cultivate the vast majority of these organisms on the other hand, it makes sense that metagenomics has become one of the key methods to study the composition and functions of complex microbial communities. The rapid advance of massively parallel sequencing and high-throughput screening technologies will enable even faster and cheaper access to environmental sequence datasets in the future, but connecting the metagenomic data with the physiology of the microorganisms and the environmental data remains challenging, and it will be crucial that the development of experimental setups and bioinformatic tools keep pace in order to be able to derive meaningful conclusions from metagenomic sequence data.

Metalloprotein (broader term)

Definition

Enzyme protein containing one or more metal cofactor(s).

Introduction

Metalloenzymes are enzyme proteins containing metal ions (metal cofactors), which are directly bound to the

protein or to enzyme-bound nonprotein components (prosthetic groups). About one-third of all enzymes known so far are metalloenzymes (see Holm et al., 1996 for a general overview). Besides enzymes, other metalloproteins are involved in non-enzyme electron transfer reactions (cytochromes), may act as storage (e.g., ferritin for iron) or transport proteins (e.g., transferrin for iron). In the latter groups of proteins, the metal storage is reversible and the metal is a temporary component. Also ribozymes, i.e., RNA molecules with enzyme function may contain structurally and/or functionally important metal ions (mostly divalent metal ions such as Mg^{2+}) and may be therefore termed as metalloenzymes in a broader sense (Sigel and Pyle, 2007).

Though primarily focused on enzyme proteins, i.e., proteins acting as biocatalysts in biochemical reactions, also important non-enzyme proteins (without catalytic activity in the strict sense) and their metal centers are discussed in this article.

In enzyme catalysis, transition metals are of special relevance due to their redox activity, and/or a high charge density, which allows the polarization of enzyme substrates. Vanadium, molybdenum, tungsten, manganese, iron, cobalt, nickel, and copper metal centers have been characterized so far; the metal atoms can occur in mono-, di-, and multinuclear centers with nitrogen, oxygen, and sulfur atoms of the polypeptide chain as possible ligands (Holm et al., 1996; Degtyarenko, 2000; Wilson et al., 2004; Table 1). For analysis of metal centers in proteins, spectroscopic tools for the investigation of small molecules are of relevance, namely electron paramagnetic resonance (EPR) or the related electron-nuclear double resonance (ENDOR) spectroscopy, electron spin resonance (ESR), resonance Raman or Mössbauer spectroscopy. Data obtained from X-ray protein crystallography are inevitable to locate the metal center and its ligands inside a protein molecule. Combination of proteomic approaches with technologies for elemental trace analysis (inductively coupled plasma mass spectrometry or ICP-MS) introduced tools for determination of the entire set of metalloproteins (the metalloproteome) and/or all trace metals (metallome) in an organism (Szpunar, 2005; Barton et al., 2007).

Metalloenzymes in early evolution

In early evolution, precursors of metal enzymes may have played a key role in catalytic reactions relevant for the synthesis of prebiotic macromolecules. According to the hypotheses originally postulated by Wächtershäuser, surface-bound iron, cobalt, nickel, and other transition metal centers with sulphido, carbonyl, and other ligands were catalysts involved in the synthesis of macromolecular compounds by carbon fixation, thus promoting growth of organic “superstructures” (Wächtershäuser, 1990). The metabolic type of this prebiotic scenario was chemolithoautotrophic, driven by the reducing potential of the outflow from deep-sea hydrothermal vents during

Metalloenzymes, Table 1 Abundance of some metals in bacterial and algal organisms in g/100 g (dry weight) and some important key functions in enzymes (Barton et al., 2007)

Element	Algae	Bacteria	Some specific roles in enzymes
K	1.81	1.7	Protein stabilization
Ca	0.55	0.1	Protein stabilization
Mg	0.35	0.25	Protein stabilization
Fe	0.011	0.015	O ₂ transport, storage and/or activation; electron transport; superoxide breakdown
Mn	0.006	0.005	O ₂ evolution; peroxide and superoxide breakdown
Zn	0.001	0.005	Protein stabilization; hydrolytic cleavage
Cu	0.0007	0.001	O ₂ transport, storage and/or activation; electron transport; superoxide breakdown
Mo	0.0001	0.001	Oxygen transfer; N ₂ activation
Co	0.0003	0.001	Free radical reactions; nucleophil

**Metalloenzymes, Figure 1** Various metal centers (from Degtyarenko, 2000) (a) mononuclear iron center (nitrile hydratase), (b) mononuclear magnesium center (Ni-Fe-hydrogenase from *Desulfovibrio*), (c) dinuclear copper center (oxyhemocyanin), (d) polynuclear iron-sulfur center, (e) heme iron coordination (cytochrome P450), and (f) molybdopterin (sulfite oxidase).

the Hadean period. Namely, the acetyl-CoA biosynthetic pathway may be seen as a model for prebiotic energy metabolism, since in this pathway enzymes and other proteins with FeS and (Fe,Ni)S centers are involved (acetyl CoA-synthetase/carbon monoxide dehydrogenase, hydrogenases, ferredoxin); these metal centers are in principle the cubic Fe₄S₄ as well as (SNiS)(Fe₄S₄)(SFeS) units of greigite (Fe(II)Fe(III)₂S₄). Later on in evolution, the prebiotic metal centers became parts of peptides and, finally, defined proteins (Wächtershäuser, 1990; Russell and Martin, 2004). Among all metalloproteins, iron metalloproteins and, within this class, iron-sulfur proteins

are supposed to be the most important group and ubiquitous in organisms.

Besides FeS-centers, tetrapyrroles as metal-chelating prosthetic groups are interesting from the evolutionary viewpoint. Tetrapyrroles are as cyclic molecules (corrins and porphyrins; e.g., Figure 1e) ideal chelators of cobalt, copper, iron, manganese, and nickel. At the same time, the highly conjugated porphyrin molecules increase the catalytic activities of transition metal ions in electron transfer reactions by several orders of magnitude. Since porphyrins are present in all kingdoms of life, they must have evolved early in evolution, perhaps even in the

prebiotic state. As for FeS centers, the prosthetic groups are found in otherwise completely unrelated metalloproteins, such as methyl-coenzyme M reductase and chlorophylls (see below; Mauzerall, 1998).

Until the Paleozoic era, availability of bioessential transition metals changed by several orders of magnitude. Whereas Cu, Zn, Ni, and Mo concentrations increased in the ocean water, Co, Mn, and particularly iron decreased by several orders of magnitude during the Proterozoic eon (Anbar, 2008). These changes must have had an impact on the biogenic production of greenhouse gases such as nitrous oxide (Cu-dependant) or methane (Ni-dependant) and, hence, respective impact on global climate. The molybdenum cofactor (see below), in particular, plays a key role in the biological nitrogen cycle. It may even be speculated that molybdenum availability in oceans had a tremendous impact on early evolution. Under the reducing atmosphere, molybdenum was depleted in the proterozoic ocean, generating a “bottleneck” for the nitrogen cycle. The low availability of nitrogen must have had a retarding effect of total biomass production of all organisms (especially non-nitrogen-fixing eukaryotes), until the oxidizing atmosphere also provided high molybdenum availability and stopped nitrogen limitation (Zerkle et al., 2006; Anbar, 2008). Limited molybdenum availability may also have been overcome in part by (less effective) molybdenum-independent nitrogenases. The evolutionary history of the enzymes is, however, difficult to reconstruct. There is no phylogenetic evidence that these “alternative” nitrogenases preceeded the molybdenum-dependant enzymes (Raymond et al., 2004).

In recent oceans, though, most metal ions relevant for enzyme metal centers are just present in trace amounts in seawater, and/or form hardly soluble salts. Thus, most organisms utilize specialized chelating compounds, uptake and transport systems for metal ion intake.

Biomimetic metalloenzymes

Metal centers from enzyme proteins may give essential data for the design of biomimetic enzymes in bioorganic synthesis. Biomimetic metal centers from enzymes such as cytochrome oxidases (with Fe-porphyrin), catechol oxidase (based on Mn(IV)-complexes with *o*-aminophenol ligands), or hydrogenase (based, e.g., on six-coordinate Ni-Ru-centers with hydrogen as one of the bridging ligands for NiFe hydrogenase) reveal the biotechnological potential of catalysts derived from biological metal enzymes (Zbaida and Kariv, 1989; Chaudhuri et al., 2005; Song et al., 2005; Ogo et al., 2007).

Classification of metalloenzymes

Since metalloenzymes are found in all enzymes families, simple classification of metal-containing subgroups based on sequence similarities cannot be applied. Reasonable classification schemes are based upon the bioinorganic motifs (Degtyarenko, 2000; Figure 1), i.e., the metal atom and its ligands (Degtyarenko and Contrino, 2004).

Metal centers may be classified by the number of bound metal atoms as mononuclear (for one metal atom, Figure 1a and b) or polynuclear (more than one metal atom, Figure 1c and d) with endogenous ligands (i.e., the polypeptides of the enzyme molecule form a mostly polydentate coordination shell) or exogenous ligands (non-protein component of a conjugated protein such as heme or molybdopterin; Figure 1e and f).

The description given below is, for the sake of simplicity, based on the central atoms. It has to be kept in mind that different metal atoms can be bound to identical or similar bioorganic motifs (e.g., cobalt, copper, iron, magnesium, and nickel by porphyrins or corrins), and different motifs coordinate the same type of metal atom (e.g., either molybdopterin or Fe₇MoS₉ homocitrate cofactor for molybdenum; see below).

Metal centers in metalloenzymes and other metal proteins

Mononuclear iron proteins are oxidoreductases (e.g., aromatic amino acid hydroxylases, aromatic ring cleavage dioxygenases, Fe-superoxide dismutase, lipooxygenases, nitrile hydratase, and Rieske oxygenases), or involved in electron transfer (desulfiredoxins, rubredoxins, and photosynthetic reaction centers). The amino acid ligands are mostly histidine and/or cysteine such as in nitrile hydratase with three cysteine residues and two amide nitrogens (Figure 1a). *Diiron carboxylate proteins* bind a coupled binuclear iron center using, e.g., four carboxylate and two histidine residues. Oxidoreductases (alkene hydroxylase, methane monooxygenase, and phenol hydroxylase), iron storage (bacterioferritin, ferritin), and oxygen storage/transport proteins are members of this group (hemerythrin, myohemerythrin).

Hemoproteins are characterized by an iron porphyrin as prosthetic group (Figure 1e). While four of the iron ligands are occupied by the porphyrin ring, the other two are used for binding of the protein. Hemoproteins are oxidoreductases (catalases, peroxidases), electron transfer proteins (cytochromes), or oxygen transport and storage proteins (globins) (Nordlund and Eklund, 1995; Que and Ho, 1996).

Iron-sulfur proteins are characterized by the presence of iron-sulfur clusters containing sulfide-linked di-, tri-, and tetrairon centers in variable oxidation states (Figure 1d). Iron-sulfur clusters are found in ferredoxins, NADH hydrogenases, dehydrogenases, cytochrome c reductases, nitrogenases, and other proteins. Proteins with iron-sulfur clusters have key roles in nearly all respiratory chains, either in bacteria and archaea or in mitochondria of eukaryotic organisms. Other functions include catalysis of stereo-specific isomerization of citrate to isocitrate (aconitase) in the tricarboxylic acid cycle or the redox-dependent gene regulation. The simplest iron-sulfur cluster type consists of two iron ions bridged by two sulfide ions and is coordinated by four cysteinyl ligands or by two cysteines and two histidins. The oxidized proteins

contain two Fe^{3+} ions, whereas the reduced proteins contain one Fe^{3+} and one Fe^{2+} ion. These species exist in two oxidation states, Fe(III)_2 and Fe(III)Fe(II) . Besides $[\text{2Fe-2S}]$, $[\text{3Fe-4S}]$, $[\text{4Fe-4S}]$, or $[\text{8Fe-7S}]$ clusters are known (Bertini et al., 1995).

Also in *copper-containing proteins*, several metal center types occur. Similar to iron proteins, copper proteins are involved in oxygen transport or activation processes and electron transport. *Type I copper centers* have a single copper atom coordinated by two histidine residues and a cysteine residue in a trigonal planar structure and a variable axial amino acid ligand. Type I proteins are, e.g., ascorbate oxidase, ceruloplasmin, laccase, nitrite reductase, auracyanin, and azurin. *Type II copper centers* are square planar coordinated by N or N/O ligands (e.g., in galactose oxidase). *Type III centers* consist of two copper atoms (Figure 1c), each coordinated by three histidine residues (catechol oxidase, hemocyanins, tyrosinase). The *copper A center* in cytochrome c-oxidase consists of two copper atoms, coordinated by two histidine imidazole residues, methionine, carbonyl-oxygen, and two cysteine-S bridging the copper atoms. In cytochrome oxidase *copper B centers*, the copper atom is coordinated by three histidine imidazole residues. The *four copper atom center* of nitrous oxide oxidase is coordinated by seven histidine residues. The four centers are bridged by one sulfur atom. Besides cytochrome oxidase, also other copper proteins are frequently oxygenases or dioxygenases (monoamine-oxidase, laccase, caeruloplasmin, superoxide-dismutase, hemocyanine) (Adman, 1991).

Zinc proteins represent the third large group of metalloproteins, with one, two, or three zinc ions. Zinc ions in proteins are classified as catalytic, co-catalytic, and structural, where zinc is either directly involved in the opening or closing a chemical bond, or zinc acts in the catalytic reaction in concert with other metal ions, or zinc ions maintain structural integrity of the enzymes. Zinc ions in catalytic sites are generally coordinated to the side chains of three amino acid residues and a water molecule. In structural zinc sites, the ion is coordinated by four amino acid side chains in a tetrahedral symmetry. With a filled *d* orbital, zinc ions do not participate in redox reactions, but rather function as Lewis acids to accept a pair of electrons, which is favorable for reactions like proteolysis or the hydration of carbon dioxide. Important zinc-containing enzymes are the alcohol dehydrogenase (containing both a catalytic and a structural zinc site), metalloproteases, and carbonic anhydrases with catalytic zinc sites. Cocatalytic zinc sites are found in superoxide dismutases, phosphatases aminopeptidases, and β -lactamases. In alcohol dehydrogenases, the zinc catalytic site is responsible for binding of the hydroxyl group oxygen from the alcohol substrate by replacing the zinc-bound water molecule (Lipscomb and Sträter, 1996; McCall et al., 2000).

Nickel in metalloenzymes occurs as Ni-4Fe-5S (e.g., nickel-containing CO dehydrogenases), coordinated in a *tetrapyrrole complex* (e.g., in methyl-coenzyme

M reductase with glutamine as axial ligand) and as *dinuclear NiNi or NiFe complexes* (e.g., in hydrogenases and urease) or a $[\text{4Fe-4S}]^{2+}$ cluster bridged by a cysteine thiolate to a dinuclear NiNi center (acetyl-CoA synthase). Nickel-containing CO-dehydrogenases occur in anaerobic bacteria and archaea (CO-dehydrogenases from aerobic bacteria are molybdopterine enzymes), whereby CO is bound by the nickel atom and hydroxyl oxygen (from water) is transferred to the bound carbon atom. After CO_2 is released, nickel is reduced ($\text{Ni}^{2+} \rightarrow \text{Ni}^+$) and transfers two electrons to ferredoxin. In the methyl-coenzyme M-reductase reaction, methane and a heterodisulfide are generated from the substrate methyl coenzyme M that reacts with coenzyme B (7-thioheptanoylthreoninephosphate). In nickel-iron hydrogenases, nickel of the Ni-Fe center is coordinated by one apical and three equatorial S-cysteins. The Ni-Fe hydrogenases catalyze both H_2 evolution and uptake in vitro, with cytochromes acting as either electron donors or acceptors. Acetyl-CoA synthase catalyzes the reversible formation of acetyl-CoA from carbon monoxide, a methylated corrinoid protein and coenzyme A, and is complexed with a nickel CO dehydrogenase (Ermler et al., 1998).

Manganese in metalloenzymes may also act as a simple Lewis acid catalyst. Manganese (normally Mn(II)) can also be oxidized to the (III)- or (IV)-state in biological systems, which allows redox-cycling reactions. *Manganese metal centers* may be mono-, bi-, tri-, or tetranuclear. Mn-superoxide dismutases (SODs) exhibit *mononuclear centers* and are antioxidant metalloenzymes catalyzing the redox disproportionation of the superoxide radical, O_2^- . SOD decomposes the highly reactive superoxide anion by a two-step disproportionation reaction which generates oxygen hydrogen peroxide. The active site manganese is five-coordinate, with the metal ligands arranged in distorted trigonal bipyramidal geometry. Two known enzymes with *binuclear centers* are arginase and manganese catalase. Arginase catalyzes the conversion of arginine to urea and ornithine. The manganese ions are five- and six-coordinate, respectively, with square-pyramidal and (distorted) octahedral coordination symmetries. The metal centers are interconnected by a solvent-derived hydroxide and carboxylate residues. This metal-bridging hydroxide acts as nucleophile that attacks the arginine guanidinium carbon. Other binuclear manganese enzymes are aminopeptidase P from *Escherichia coli* and the dinitrogenreductase-activating glycohydrolase from *Rhodospirillum rubrum*.

One of the most important biochemical catalytic reactions in our biosphere, the oxygen-generating photolysis of water, is brought about by the *tetranuclear manganese cluster* in oxygenic photosynthesis of cyanobacteria, eukaryotic algae, and higher plants. In oxygenic photosynthesis, water is oxidized by a cluster of Mn ions. Light is captured by antenna chlorophyll and funneled to the primary reaction center, which contains chlorophyll (P680). The oxidized P680 first oxidizes a redox-active tyrosine. Subsequent oxidation of the Mn cluster occurs via this

generated tyrosine radical. The enzyme can exist in five oxidation levels, corresponding to various oxidation states of the cluster (Wiegardt, 1994; Yocum and Pecoraro, 1999; Carrell et al., 2002).

Molybdenum and *tungsten* enzymes catalyze basic metabolic reactions in the nitrogen, sulfur, and carbon cycles. With the exception of the nitrogenase cofactor, molybdenum is associated with the heterocyclic pterin derivative (molybdopterin) that contains a mononucleate center, coordinated to the thiols of the cofactor (Figure 1f). These *molybdenum-cofactor-containing (MoCo) enzymes* catalyze the transfer of an oxygen atom, derived from or incorporated into water, to or from a substrate in a two-electron redox reaction. Three classes of MoCo enzymes are now distinguished, represented by xanthine oxidase and sulfite oxidase families (with single pterin ligands and either ligand-Mo(VI)OS(OH) or ligand-Mo(VI)O₂(S-cys) cores), and DMSO reductase family (with two pterin ligands). The *nitrogenase molybdenum metal center* is not related to the pterin derivatives. In molybdenum nitrogenases, each Mo forms a part of a polynuclear cluster containing 1 Mo, 7 Fe, and 9 S organized into an elongated structure. Within the protein the terminal Fe of the cluster is coordinated by a cysteine residue, while the Mo is coordinated by a histidine residue and a homocitrate ligand.

Tungsten, which lies in the chromium group of the periodic system immediately below molybdenum exhibits similar chemical properties and is complexed in a similar way to the pterin cofactors as described for molybdenum. Due to the higher sensitivity of tungsten toward high redox potential, tungsten enzymes are found in (thermophilic) anaerobic bacterial and archaeal microorganisms (Hille, 2002; Williams and Fausto da Silva, 2002).

Cobalt is the central metal ion in the tertrapyrrol *corrin ring* in the coenzyme B₁₂. Similar to porphyrin rings, four coordination sites are provided by the corrin ring. The B₁₂-bearing enzymes catalyze either the transfer of methyl groups between two molecules or isomerization reactions, i.e., rearrangements of hydrogen atoms with concomitant exchange of a substituent (e.g., an hydroxyl group) between two adjacent carbon atoms in a molecule. In *non-corrin cobalt enzymes*, cobalt is complexed by aminoacids such as in nitrile hydratase (catalyzing the hydration of nitriles to amides; Kobayashi and Shimizu, 1999).

Vanadium occurs as V(III), V(IV), or V(V) in biological systems. The respective enzymes catalyze the two-electron oxidation of a halide by hydrogen peroxide. Besides the vanadium-containing enzymes, also heme-containing haloperoxidases and metal-free enzymes are known. In tunicates (ascidians) vanabin binds 20 V(IV) ions. However, the role of vanabins in vanadium accumulation by the ascidian has not yet been determined. In vanadium nitrogenases, vanadium, instead of molybdenum is present in a FeVCo-center (Michibata et al., 2003; Crans et al., 2004).

Though frequently not classified as metalloenzymes in the strict sense, numerous (enzyme) *proteins bind Na⁺ and*

K⁺ ions. The structures of Na⁺ and K⁺-complexes with proteins have a variety of coordination schemes and functions. Usual coordination numbers are five and six. Though the ions are not directly involved in catalytic steps, they activate numerous enzymes. Prominent examples are Na⁺-activated β -galactosidase or the K⁺-dependent activity of pyruvate-kinase and glycerol dehydratases (Page and Di Cera, 2006).

Specific *binding of calcium ions* frequently leads to conformational changes and increased protein stability. One large family of calcium-binding proteins is denoted *EF-hand proteins*, comprising a calcium-binding structural domain ("helix-turn-helix" motif). In an EF-hand loop the calcium ion is coordinated in a pentagonal bipyramidal configuration, by atoms of the protein backbone and side chains especially of aspartate and glutamate. Examples for EF-hand proteins are calmodulin and parvalbumin. In *non-EF-hand calcium-binding proteins*, the binding motifs are not conserved, such as α -lactalbumin and thermitase (Yang et al., 2002).

Also *magnesium* has a key function in activation and stabilization of enzymes. Isocitrate lyase and glutamine synthetase are two examples of Mg²⁺-activated metabolic enzymes. Enzymes catalyzing phosphorylation of proteins typically use magnesium chelates of ATP as cosubstrate. The bound Mg²⁺ serves to facilitate nucleophilic attack at the γ -phosphate of the ATP substrate. Phosphate and phosphoryl transfer reactions require Mg²⁺ as an essential cofactor. In chlorophyll molecules of photosynthetic reaction centers, magnesium ions are coordinated in a terrapyrrole ring system and to an axial *N*-histidin, *O*-aspartate, *O*-formyl-methionin, *O*-leucin, or water as ligands (Figure 1b; Cowan, 2002).

Conclusion

Since metal centers are present in all enzyme families, and enzymes with metal centers also catalyze a wide variety of different reactions, metal enzymes cannot be assigned to a special group of enzymes or proteins. Thus it is very likely that metal centers developed early in evolution and evolved in several different lineages. Since free transition metal ions are ideal catalysts for numerous reactions in organic chemistry (and biochemistry) at moderate temperatures, they appear to be the natural "precursors" of functional enzyme proteins. Peptides and proteins are, on the other hand, ideal chelators for metal ions. Thus, protein and metal partners may have easily come together frequently during evolution.

METALLOGENIUM

Joachim Reitner
 University of Göttingen, Göttingen, Germany

Definition

Metallogenium s.str. is a star-shaped enigmatic bacterium oxidizing Mn and iron. It preferentially lives in limnic environments.

Metallogenium is a relatively large (2–10 μ m) microorganism with bacterial affinities that concentrates manganese and iron oxides in significant amounts. The genus *Metallogenium* has not yet been assigned to any taxonomic group. The cells lack rigid walls and develop flexible, tapering threads from which new cells probably arise. The organism is therefore, star-shaped and is found in various facies, predominantly in limnic environments (Figures 1 and 2). The threads are often heavily encrusted with oxides of iron and/or manganese. The oldest

Metallogenium, Figure 1 *Metallogenium personatum*. (Redrawn from Perfil'ev and Gabe, 1961.)

Metallogenium, Figure 2 *Metallogenium personatum*. (Redrawn from Klaveness, 1999.)

Metallogenium-like fabrics are known from the 1.88 Gy old Paleoproterozoic Gunflint Formation (Barghorn and Tyler, 1965).

The first detailed description of *Metallogenium* was carried out by Perfil'ev and Gabe (1961) who called the type species *Metallogenium personatum*. There is an enormous record of publications about this microorganism (Zavarin, 1964a, b; Dubinia, 1970; Schmidt

and Overbeck, 1984), and many speculations have been made about its systematic position, for example, within the Mycoplasmatales (Zavarin and Hirsch, 1974), Chlamydobacteria (Klaveness, 1977), and Hyphomicrobiales (Perfil'ev and Gabe, 1961). Clasen (1969), Schmidt and Overbeck (1984), and Zavarin (1989), suggested a relationship with the iron bacterium *Leptothrix echinata* (Beger, 1935) which shows a considerable morphological similarity to *Metallogenium*. Unfortunately, valid molecular biological examinations presently do not exist to clarify the phylogenetic position of this organism, although it is common especially in many freshwater lakes (e.g., Klaveness, 1999; Schulte, 1994). Besides *Metallogenium personatum*, which is undoubtedly a prokaryotic organism, "*Metallogenium symbioticum*" was described (Zavarin, 1964b), which is also an Mn-oxidizing prokaryote preferentially growing on fungal microorganisms (Schweisfurth, 1971).

METALS, ACQUISITION BY MARINE BACTERIA

Alison Butler, Vanessa V. Homann
 University of California, Santa Barbara, CA, USA

Definition

Oceanic bacteria produce siderophores to acquire iron. Given that the iron concentration in surface ocean water is very low, siderophores produced by marine bacteria are tailored to the physical and chemical constraints of the marine environment.

Introduction

Microbial iron uptake

Virtually, all bacteria require iron for growth. Bacteria growing under aerobic conditions utilize a variety of pathways to acquire iron, but under conditions of iron starvation, bacteria often produce siderophores (Crosa et al., 2004). Siderophores are low molecular weight, chelating compounds produced by bacteria to facilitate iron(III) uptake (Crosa et al., 2004; Kraemer et al., 2005; Butler, 2007). The Fe(III)-siderophore complex is recognized by a specific outer membrane protein receptor, which catalyzes the transport of the Fe(III)-siderophore complex across the outer membrane (Figure 1).

The study of marine microbial siderophores is relatively new (Butler and Martin, 2005), yet certain characteristic structural features have already begun to emerge: suites of amphiphilic siderophores and photoreactive Fe(III)-siderophores.

Marine Siderophores

Amphiphilic marine siderophores

One characteristic of marine siderophores is the predominance of suites of amphiphilic siderophores, comprised of a hydrophilic head group, which coordinates with Fe(III), and one of a series of hydrophobic fatty acid appendages, which confers amphiphilicity (Figure 2). Two types of suites of amphiphilic siderophores are produced by marine bacteria. The aquachelins, marinobactins, and amphibactins are amphiphilic peptidic siderophores produced by distinct genera of marine bacteria (Figure 2) (Martinez et al., 2000, 2003). The relative amphiphilicity of each of these siderophores is

Metals, Acquisition by Marine Bacteria, Figure 1 Siderophore-mediated iron uptake by a bacterium.

defined by both the number of amino acids in the peptide fraction, compared to the fatty acid chain length (e.g., C12–C18). The amphibactins with only four amino acids and relatively long C18 fatty acids are the most hydrophobic of the amphiphilic peptide siderophores. As a result, they remain cell associated and are extracted from the bacterial pellet during the isolation process (Martinez et al., 2003). In contrast, the marinobactins and aquachelins, with five and six amino acids in the head group and a predominance of the shorter fatty acids, are more hydrophilic and are thus isolated from the supernatant following centrifugation of the bacterial culture to pellet the cells (Martinez et al., 2000).

The synechobactins and ochrobactins (Figure 2) are different suites of amphiphilic siderophores, in which the head group is based on citric acid, as opposed to a peptide. The head group is thus smaller than in the peptidic amphiphilic siderophores. The fatty acids are also shorter than observed for the peptidic amphiphilic siderophores. Nevertheless, the ochrobactins are quite hydrophobic as a result of two fatty acid appendages; these siderophores remain associated with the bacterial pellet (Martin et al., 2006). The synechobactins, with

Metals, Acquisition by Marine Bacteria, Figure 2 Amphiphilic marine siderophores. Marinobactins (Martinez et al., 2000); aquachelins (Martinez et al., 2000); amphibactins (Martinez et al., 2003); ochrobactins (Martin et al., 2006); synechobactins (Ito and Butler, 2005). The boxed portion shows the hydroxamic acid group. The circled portion shows the α -hydroxyacid in β -hydroxyaspartic acid.

only one fatty acid appendage, partition between the culture supernatant and the bacterial pellet (Ito and Butler, 2005).

Photoreactive Fe(III)-siderophores

The other characteristic of marine siderophores is the predominance of α -hydroxycarboxylic acid moieties in the form of β -hydroxyaspartic acid or citric acid (Figures 2 and 3).

The Fe(III)-complex of an α -hydroxycarboxylic acid moiety is photoreactive in UV light, including natural sunlight, which is a condition experienced by the mixed layer of the upper 30–40 m of the ocean. Upon UV photolysis of the Fe(III)-siderophores containing citric acid, such as the ochrobactins (Martin et al., 2006), the synechobactins (Ito and Butler, 2005), the petrobactins (Bergeron et al., 2003; Hickford et al., 2004), and aerobactin (marine *Vibrio* sp. DS40M5) (Küpper et al., 2006; Haygood et al., 1993), citrate is oxidized to 3-ketoglutarate and Fe(III) is reduced to Fe(II). The resulting ligand photoproduct

retains the ability to coordinate Fe(III) with remarkably high stability constant as a result of the 3-ketoglutarate moiety and the remaining hydroxamic acid groups (Figure 4, for aerobactin (Küpper et al., 2006).

Other marine siderophores such as the aquachelins, the marinobactins, the alterobactins, and the pseudoalterobactins contain β -hydroxyaspartic acid as the α -hydroxycarboxylic acid group. UV photolysis of the Fe(III)-aquachelins results in ligand oxidation, specifically loss of β -hydroxyaspartic acid, as well as reduction of Fe(III) to Fe(II) (Barbeau et al., 2001). This peptide photoproduct retains the two hydroxamate groups and thus the ability to coordinate with Fe(III), although the conditional stability constant is somewhat reduced (Barbeau et al., 2001). Only catalytic amount of Fe(III) is required to effect the complete oxidation of the aquachelins in aerobic conditions, because the Fe(II) that is produced is oxidized back to Fe(III) and thus can coordinate with another apo aquachelin. The ferric complexes of the alterobactins A and B and the marinobactins are also photoreactive (Barbeau et al., 2003), although the

Metals, Acquisition by Marine Bacteria, Figure 3 Marine siderophores with α -hydroxycarboxylic acid groups. The aquachelins, marinobactins, ochrobactins, and synechobactins shown in Figure 2 also contain α -hydroxycarboxylic acid moiety. Alterobactins (Reid et al., 1993); pseudoalterobactins (Kano et al., 2003); aerobactin (Haygood et al., 1993); petrobactin (Bergeron et al., 2003); petrobactin-SO₃ (Hickford et al., 2004); vibrioferriin (Amin et al., 2007). The circled portion shows the α -hydroxyacid in citric acid.

Metals, Acquisition by Marine Bacteria, Figure 4 Reaction products in the photolysis of Fe(III)-aerobactin. (Adapted from Küpper et al., 2006).

structures of the oxidized ligands have not been completed yet. The ferric complexes of pseudoalterobactins A and B, which are chemically related to the alterobactins (Kano et al., 2003), would also be expected to be photoreactive.

Summary

The preponderance of suites of amphiphilic siderophores and of α -hydroxycarboxylic-acid-containing siderophores produced by marine bacteria suggests that these properties have evolved as common iron acquisition strategies for

marine bacteria, although details of the biological advantages conferred by these molecular properties are yet to be elucidated.

METEORITICS

Mark A. Sephton
 Imperial College London, London, UK

Definition

Meteorites are fragments of extraterrestrial material that fall on the Earth's surface. Most meteorites are parts of asteroids propelled into Earth-crossing orbits by relatively recent collisions in the asteroid belt, initiated by the gravitational effects of Jupiter's orbit. Relatively small numbers of meteorites originate from larger objects such as the Moon and Mars. The Earth acquires 10^2 to 10^3 t of such material each day, but only 1% or less arrives in pieces large enough for identification and recovery (Dodd, 1981). The surface of the meteorite usually melts and emits a glowing tail and a trail of smoke, but the interior of the meteorite is unaffected by passage through the Earth's atmosphere and remains at the temperature of interplanetary space.

Collection of meteorites

“Falls” are meteorites that have been observed to fall and were subsequently collected; “finds” are meteorites that were not seen to fall. Before the 1970s, the total number of known meteorites amounted to less than 1,000 falls and 1,706 authenticated finds. Since then, it has been recognized that certain parts of the Earth's surface preserve and concentrate meteorites. To date, tens of thousands of meteorites have been collected from the Antarctic ice. Similar numbers of meteorite fragments have also been collected from hot deserts. Most recently, telescope and camera network surveys have produced meteorites with photographed fireballs allowing the calculation of their orbits and assignment to a particular source within the solar system (Bland et al., 2009).

Chondrites

About 85% of the meteorites observed to fall on the Earth are chondrites, conglomerate rocks with an overall elemental composition similar to the Sun, if the loss of the most volatile elements is ignored. When their near solar makeup is considered alongside radiometric ages of 4.56×10^9 years, it becomes clear that chondrites are rocks formed during, or shortly after, the birth of the Sun.

The record in chondrites

Their status as some of the earliest formed solids in the solar system combined with a lack of subsequent processing ensures that chondrites represent a valuable record of extraterrestrial environments. Contributing regions include interstellar space, the solar nebula and the asteroidal meteorite parent bodies.

Carbonaceous chondrites

Of all the chondrites, the carbonaceous chondrites are considered the most primitive and these objects represent an enthralling window back in time providing views of the earliest solar system (Figure 1). The name “carbonaceous chondrite” is highly descriptive as these meteorites contain a carbon-rich matrix composed primarily of clay minerals, oxides, and organic matter, and most contain spherules of silicate glass termed chondrules.

Classification of carbonaceous chondrites

The carbonaceous chondrites are classified according to their primary and secondary characteristics (Figure 2). The primary classification (CI, CM, CR, CO, CV, CK)

Meteoritics, Figure 1 The Murchison carbonaceous chondrite.

reflects the original properties of the meteorites such as bulk chemistry and mineralogy. The label is derived from the carbonaceous chondrite accepted as the type specimen, for example, CI = Ivuna. The secondary numerical classification reflects petrographic type, which indicates the extent and type of alteration that the meteorite has undergone on its parent body.

Carbon in meteorites

The carbon in carbonaceous chondrites is present in several forms and each has its specific source region(s) (Table 1; Sephton et al., 2003). Materials like silicon carbide and graphite condensed from the atmospheres of stars that existed long before our Sun. Nanometer-sized diamonds also originate as condensation products of stellar outflows as well as from catastrophic supernova explosions. Carbonate minerals were formed in the early solar system as aqueous alteration took place on asteroids. Yet all these components are quantitatively subordinate to the main carbonaceous material in carbonaceous chondrites – organic matter.

Types of organic matter in meteorites

Much of our current understanding of meteoritic organic matter has come from investigations of the Murchison carbonaceous chondrite, approximately 100 kg of which fell in Australia in 1969 (Figure 1). Not all of the organic molecules in meteorites are present in the same form. A minor portion of the organic matter in meteorites is present as small “free” molecules, including various hydrocarbons and the biologically useful amino acids and carboxylic acids (Figure 3), but the majority of organic matter in the carbon-rich meteorites is present as a highly cross-linked organic network or “macromolecular material”.

Meteoritics, Figure 2 The classification system for carbonaceous chondrites.

Free compounds

Amino acids

The amino acids found in meteorites have attracted a great deal of attention owing to their role as building blocks for proteins. The search for amino acids in meteorites accelerated in the 1960s (Degens and Bajor, 1962; Kaplan et al., 1963) following reports of microfossils in certain samples (Claus and Nagy, 1961). Amino acids were discovered, but these initially promising results were later found to be the result of terrestrial contamination. It was only when the organic-rich Murchison meteorite fell and was rapidly analyzed that both protein and, importantly, nonprotein amino acids were found in this fresh sample (Kvenvolden

et al., 1970). Today it is known that the amino acids in Murchison are present at around 60 ppm. Compounds containing two through eight carbon atoms exist and they exhibit several features, which suggest that they are not terrestrial contaminants but are extraterrestrial and nonbiological or “abiotic” in origin. The meteoritic amino acids display broad structural diversity, a decline in abundance with increasing molecule size, and the presence of unusual and even unique molecular configurations.

A particular characteristic of amino acids is chirality or handedness. One chiral form rotates the polarized light to the left and is termed levorotatory or “L,” while the other form rotates the light to the right, and is called dextrorotatory or “D.” Chirality is important for theories that link extraterrestrial organic matter with the origin of life, because terrestrial biology preferentially generates L-amino acids whereas abiotic reactions generally have no preference and produce racemic mixtures with equal amounts of L and D forms.

The discussion of whether amino acids in meteorites were racemic (with equal amounts of L and D forms) or nonracemic (with a preference for one or the other) began in the 1950s and continued through the 1960s, (e.g., Mueller, 1953; Nagy et al., 1964) but early results implied that the dominance of L forms was caused by terrestrial contamination and analytical artefacts. Yet following the fall of Murchison in 1969, four protein and seven

Meteoritics, Table 1 The carbon-bearing components in carbonaceous chondrites

Carbon-bearing component	Abundance (wt. %)	Environment of formation
Organic matter	2.0	Interstellar space, solar nebula, asteroids
Carbonate	0.2	Asteroids

Meteoritics, Figure 3 Some free compound classes and examples found in carbonaceous chondrites.

nonprotein amino acids were found to be racemic (Kvenvolden et al., 1970, 1971). More modern analyses have reinvigorated the debate over the racemic nature of meteorite amino acids and a slight L-excess in both protein and nonprotein amino acids has been reported (Engel and Nagy, 1982; Pizzarello and Cronin, 2000).

Proposed mechanisms for producing this L-excess in meteoritic amino acids rely on selective destruction of the right-handed form of the amino acids. Currently, popular hypotheses involve ultraviolet circularly polarized light from a neutron star or reflection nebulae (Bailey, 2001; Bonner and Rubenstein, 1987). It is a necessary consequence of this theory that at least some amino acids were already formed in interstellar space so that preferential destruction of D-amino acids could take place. The recent detection of the simplest amino acid, glycine, in interstellar spectra supports this assertion (Kuan et al., 2003).

Carboxylic acids

Carboxylic acids are another type of biologically useful molecule found in meteorites. In life, they are a convenient and compact store of energy and are common cell membrane molecules. Carboxylic acids in Murchison contain between two and five carbon atoms and display complete structural diversity, a general decrease in abundance with increasing carbon number, and an equal concentration of branched and straight-chain isomers (Lawless and Yuen, 1979; Yuen and Kvenvolden, 1973). The monocarboxylic acids are present in a much higher concentration (332 ppm) than the amino acids and are the most abundant solvent extractable compounds. A structurally diverse suite of dicarboxylic acids containing up to nine carbon atoms are also present in much smaller amounts (26 ppm) (Lawless et al., 1974).

Hydroxyacids

Hydroxycarboxylic acids (or hydroxyacids) in carbonaceous chondrites contain up to nine carbon atoms and are structurally diverse and present in concentrations of 15 ppm (Peltzer and Bada, 1978). Intriguingly, the hydroxyacids correspond in structure to the more abundant amino acids suggesting that some hydroxy and amino acids may have been produced together on the parent asteroid. The relevant chemical reaction is known as the Strecker-cyanohydrin synthesis. Hydrogen cyanide and aldehydes combine in aqueous solution to produce hydroxyacids but if ammonia is also present then the products become amino acids.

Sugar-related compounds

Collectively, sugars and their related compounds are called polyhydroxylated compounds or "polyols." They are compounds containing a number of hydroxyl (OH) groups attached to their carbon skeleton. Sugars are

important biologically as a source of energy for organisms and, when combined to form larger molecules, they can act as food stores and give structural support. Experiments in the 1960s detected polyols in carbonaceous chondrites, but terrestrial contamination was implied (Degens and Bajor, 1962). More recent experiments on Murchison have discovered a number of sugar-related compounds (sugars, sugar alcohols, and sugar acids) in similar abundances to the amino acids (Cooper et al., 2001). The Murchison polyols display many of the features of extraterrestrial compounds. Progressively larger polyols become less abundant, display almost complete structural diversity, and contain some terrestrially rare compounds implying an abiotic source.

Aliphatic and aromatic hydrocarbons

Short aliphatic molecules in Murchison are present in amounts of 1.4 ppm and display many nonbiological features, which imply they are indigenous to the meteorite, such as structural diversity and a decrease in amount with increasing molecule size (Yuen et al., 1984). Aromatic hydrocarbons, in free form are present in carbonaceous chondrites at around 30 ppm (Pering and Ponnamperna, 1971). Compound sizes range from one to seven aromatic rings with the smaller compounds generally being most abundant (Sephton et al., 1998).

Amines and amides

Amines are derivatives of ammonia (NH₃) where hydrogen atoms are replaced by other structures. In Murchison, amine concentration is 8 ppm, amounts of individual amines decrease with increasing carbon number and structural diversity is observed with almost all amine isomers with up to five carbon atoms present (Pizzarello et al., 1994).

Two possible sources of the amines in Murchison have been proposed: they may be directly inherited from the presolar molecular cloud, an assertion supported by the detection of methylamine in interstellar space, or as with the hydroxyl acids, the amines may share a common origin with the amino acids. By simply removing the carboxylic acid group of amino acids, 16 of the 20 amines can be made, a reaction that would take place if the molecules were heated on their parent asteroid.

Amides are structurally analogous to carboxylic acids and, in Murchison, the amide equivalents of monocarboxylic acids, dicarboxylic acids, and hydroxyacids are found in concentrations greater than 70 ppm (Cooper and Cronin, 1995). The amides display complete structural diversity up to and including molecules with eight carbon atoms, a decline in abundance with carbon number, and the presence of many compounds with no terrestrial source. Cyclic amides (lactams) are less abundant (2 ppm) but they are very interesting to

investigators of the origin of life. The chemical structures of cyclic amides permit hydrogen-bonded pair formation and may have acted as parts of a primitive genetic coding apparatus, possible forerunners of the present day nucleic acids.

Nitrogen heterocycles

Another compound class essential for terrestrial life is that of the nitrogen heterocycles. Some of these compounds are building blocks for nucleic acids that store genetic information. The possible presence of nitrogen heterocycles in water extracts of carbonaceous meteorites was first reported in the early 1960s but the initial optimism was dispelled when they turned out to be laboratory contaminants (Oró, 1963). Later work did confirm the presence of nitrogen heterocycles in meteorites such as Murchison and several classes, including purines, pyrimidines, quinolines/isoquinolines, and pyridines were found. All of the purines and pyrimidines found are biologically common and together account for 1.3 ppm in Murchison (Stoks and Schwartz, 1979, 1981). The quinolines, isoquinolines, and pyridines are structurally diverse, contain a large number of isomeric alkyl derivatives, and are present at concentrations of 7 ppm (Pizzarello et al., 2001; Stoks and Schwartz, 1982). Recent work has confirmed the presence and extraterrestrial origin of xanthine and uracil in the Murchison meteorite (Martins et al., 2008).

Sulfur heterocycles

Murchison contains small amounts of sulfur-containing compounds such as thiophenes, benzothiophenes, dibenzothiophenes, and benzonaphthothiophenes. The abundance pattern of thiophenes in Murchison is markedly different from those in terrestrial sediments, indicating an abiotic origin for these molecules (Shimoyama and Katsumata, 2001).

Phosphonic and sulfonic acids

Phosphorus compounds have many biological roles and play a part in cell membranes, energy transactions during metabolism, and the storage and transfer of genetic information. Sulfur compounds are also common in living systems and take part in key biochemical reactions. In Murchison, a series of alkyl phosphonic acids and alkyl sulfonic acids with up to four carbon atoms have been detected (Cooper et al., 1992). As observed for many of the other compound classes in Murchison, the sulfonic and phosphonic acids display an exponential decline in amount with increasing carbon number and exhibit complete structural diversity.

Macromolecular materials

The solvent soluble substances are only trace components, yet they are often the focus of studies on meteorite organic

matter due to their analytical amenability. Essentially, the macromolecular materials can be considered as a cross-linked agglomeration of some of the free compounds but with an overwhelming dominance of aromatic hydrocarbons. The macromolecular materials are generally assumed to be completely indigenous to their meteorite host due to their high molecular weight and immobility.

As the major organic component, the macromolecular material is key to theories of the origin of meteoritic organic matter as a whole. Hence it is interesting to consider that meteoritic organic matter is often compared with that observed in interstellar space. Some scientists believe that the molecular cloud that collapsed to form the solar system bequeathed a significant amount of interstellar organic matter, aliquots of which are preserved in primitive asteroids and the meteorites derived from them. For many years, only one- to four-ring polycyclic aromatic hydrocarbons (PAH) were commonly observed in Murchison macromolecular material breakdown products (Sephton et al., 1998), which contrasted sharply with the greater than 20-ring PAH proposed for the interstellar medium (Pendleton and Allamandola, 2002). Recently, using modern analytical techniques the meteoritic macromolecular material has yielded more information. Up to seven-ring PAH units have been liberated from the macromolecular material in Murchison and it appears that even larger entities are present in the experimental residue (Sephton et al., 2004). These discoveries partly reconcile the apparent disharmony between the meteoritic and interstellar organic inventories and point to a partly presolar origin for this abundant organic component.

Terrestrial contamination

Although some compound classes in meteorites may contain a record that extends back to interstellar environments before the solar system formed others can be much more recent in the form of terrestrial contamination. Unusual and subtle contamination sources exist and an example is provided by data from the Orgueil carbonaceous chondrite, which has a long curation history since its fall in 1864. Terpene-related compounds have been identified in this meteorite (Watson et al., 2003) and these compounds are structurally specific, and are unlikely to be produced by abiotic reactions. Terpenes are common in essential plant oils, used extensively in cleaning products, and may have percolated their way into the porous Orgueil stones.

A more widespread type of terrestrial contaminant is provided by the long-chain aliphatic hydrocarbons (normal alkanes) in meteorites (Sephton et al., 2001). Unlike the short-chain aliphatic hydrocarbons, the normal alkanes are structurally specific with all carbon atoms arranged in a straight chain. Normal alkanes in meteorites were first detected in Orgueil and were attributed to extraterrestrial biology based on similar distributions

for molecules in the meteorite and those found in butter and marine sediments (Nagy et al., 1961). Subsequent analyses on many different meteorites led to the discovery that these compounds were present in several tens of ppm, were concentrated near to the surfaces of samples, and that they were frequently associated with other, obviously terrestrial, compounds (Oró et al., 1966). A subsequent revival in the belief that these compounds were indigenous occurred when normal alkanes were interpreted as products of an abiotic catalytic reaction called the Fischer–Tropsch synthesis (Studier et al., 1968). Modern measurements of individual normal alkanes reveal terrestrial values that are distinct from the majority of meteoritic organic matter (Sephton et al., 2001) and imply that normal alkanes are simply contributions from our terrestrial environment once the meteorite has fallen on the Earth.

The location of organic matter in meteorites

In chondrites, organic matter is present within the fine-grained inorganic meteorite matrix, which contains evidence of alteration by liquid water on the parent asteroid. Hence, a general relationship between extraterrestrial organic matter and inorganic aqueous alteration products in carbonaceous chondrites has been recognized for some time. Recently, however, it has been discovered that the association is highly specific to a particular inorganic phase – clay minerals (Pearson et al., 2002). Clay minerals, therefore, may have trapped and concentrated organic matter in the early solar system and organic–inorganic interactions may have played a role in the assembly of increasingly complex organic entities 4.56×10^9 years ago.

Relevance to the origin of life on Earth

With the recognition that meteorites contain many biologically useful molecules it is enlightening to consider that the amounts of organic matter extraterrestrial objects can deliver to the Earth's surface are considerable. For example, calculations indicate that comet Halley contains organic matter equivalent to approximately 10% of the current biomass of the Earth (Greenberg, 1993). A connection between life and extraterrestrial material was first proposed in the early 1960s by the biochemist Jan Oró (Oró, 1961). It was suggested that extraterrestrial objects may have seeded the early Earth with an extensive list of ingredients for use in the recipe of life. Modern theories imply that the early Earth had a nonreducing atmosphere composed mainly of carbon dioxide and nitrogen in which the in situ generation of organic matter would be rather sluggish and inefficient. Even if only a small fraction of the molecules delivered by extraterrestrial infall proved biologically relevant, they would have had a significant impact on the prebiotic chemistry of the Earth.

Outlook

Until space missions begin to return large quantities of extraterrestrial material back to the Earth for analysis in laboratories, meteorites will remain the most accessible and most frequently studied objects to reveal the origin and evolution of the solar system. In particular, the study of carbonaceous meteorites, which contain bona fide prebiotic organic matter is likely to remain our most important means of determining how chemical evolution led to the origin of life.

Methanotrophy

Definition

Methane oxidation is a microbial metabolic process for energy generation and carbon assimilation from methane that is carried out by specific groups of bacteria, the methanotrophs. Methane (CH_4) is oxidized with molecular oxygen (O_2) to carbon dioxide (CO_2).

Biochemical basis

Methanotrophy is the microbially mediated process of the oxidation of CH_4 with O_2 to methanol, formaldehyde, formate, and finally CO_2 (Figure 1) (Hanson and Hanson, 1996; Madigan et al., 2003; Bowman, 2006). The process is performed by a specialized group of bacteria (qv), the methanotrophs (CH_4 oxidizing bacteria). They are a subgroup of the methylotrophs, bacteria capable of utilizing single-carbon compounds (Bowman, 2006).

Methane is both the energy source (electron donor) and the sole or partial carbon source for methanotrophs. Aerobic oxidation of methane requires specific enzymes, most importantly methane monooxygenase (MMO), which catalyzes the first step in the reaction: the oxidation of methane with molecular oxygen to methanol and water. Two forms of this enzyme are known: particulate methane monooxygenase (pMMO), which is ubiquitous in methanotrophs and contains copper, and the iron-containing soluble methane monooxygenase (sMMO) (Hanson and Hanson, 1996). The reaction mediated by MMO requires additional electrons, which are supplied by cellular redox carriers such as cytochrome C (for pMMO) or NADH (sMMO). Energy is conserved in the subsequent stepwise oxidations of methanol, formaldehyde, and formate. In these reactions, electrons are donated back to a membrane-bound electron transport chain (see Chapter *Aerobic Metabolism*) via a pyrroloquinoline quinone cofactor to cytochrome C (methanol dehydrogenase) or NAD (in formaldehyde oxidation systems and formate dehydrogenase). Electron flow through the membrane ultimately produces a proton motive force that is converted to the cellular energy carrier ATP by the ATPase enzyme complex. O_2 is the terminal electron acceptor (see Chapter *Aerobic Metabolism*) (Figure 1) (Madigan et al., 2003). Thus, aerobic methane oxidation can be considered a special case of aerobic

Methane Oxidation (Aerobic), Figure 1 Pathway of aerobic methane oxidation for energy conservation and carbon assimilation in Type I and II methanotrophs. pMMO, particulate methane monooxygenase; MDH, methanol dehydrogenase; FAox, formaldehyde oxidation system (tetrahydrofolate- or methanopterin-dependent) FDH, formate dehydrogenase. Methane is oxidized with oxygen by pMMO, a step which requires reducing equivalents (e.g., from NADH) supplied by later oxidations in the pathway. Energy is generated by shuttling electrons generated in the subsequent oxidations of methanol (CH_3OH), formaldehyde (CH_2O), and formate (HCOO^-) through a membrane-bound electron transport chain that creates a proton gradient across the cell membrane (proton motive force) that can be converted into ATP by ATPase (oxidative phosphorylation). Formaldehyde (CH_2O) is the starting point for carbon assimilation via the ribulose monophosphate or serine pathways.

respiration. Differences between methanotrophs are thought to exist regarding the enzymes used, especially with regard to formaldehyde oxidation, where different systems are known (Lidstrom, 2006).

Methanotrophs

Most known methanotrophs fall into two well-defined phylogenetic groups belonging to the gamma- (Type I methanotrophs) and alpha-proteobacteria (Type II) that are also distinguished by morphological traits and differences in carbon assimilation (Hanson and Hanson, 1996; Madigan et al., 2003; Bowman, 2006). Both types share the characteristic extensive intracytoplasmic membrane system (ICM), which is the site of methane oxidation. However, in Type I methanotrophs, the ICM occurs as disk-shaped membrane stacks within the cell, while in Type II methanotrophs, the ICM is located around the periphery of the cell. Both groups are strict aerobes and obligate methylotrophs. The presence of soluble methane monooxygenase (sMMO) seems to be mostly limited to Type II methanotrophs (Hanson and Hanson, 1996; Bowman, 2006). Type I and II methanotrophs employ different carbon assimilation strategies, although both incorporate methane carbon at the level of formaldehyde (Figure 1). Type I methanotrophs use the ribulose monophosphate pathway and obtain all their carbon from methane. Type II methanotrophs use the serine pathway, which in addition to formaldehyde incorporation further involves fixation of one molecule of CO₂ per molecule of formaldehyde assimilated. The former pathway is energetically more favorable, requiring only 1/3 ATP per molecule formaldehyde fixed, instead of 1 ATP and reducing power for the serine pathway. This is in accordance with the observed higher growth rates in Type I methanotrophs (Madigan et al., 2003). Most methanotrophs can also grow using other single-carbon compounds, e.g., methanol, which is the first intermediate of methane oxidation.

Within the Type I methanotrophs, the genera *Methylosphaera*, *Methylobacter*, *Methyломicrobium*, *Methylomonas*, *Methylococcus*, and *Methylocaldum* have been described. The latter two genera are often distinguished as “type X methanotrophs,” as they are phylogenetically and morphologically distinct from the other Type I genera. The cultivated type II methanotrophs belong to the genera *Methylosinus* and *Methylocystis* (Bowman, 2006). Environmental clone libraries suggest the existence of additional, yet uncultured, genera. Recently, acidophilic methanotrophs belonging to the *Verrucomicrobia* phylum have been isolated, showing for the first time that not all methanotrophs belong to the proteobacteria and that methanotrophs are phylogenetically more diverse than previously thought (Dunfield et al., 2007; Pol et al., 2007). The genome sequence of one isolate revealed the presence of pMMO genes (pmoA), but lacked homologs to known methanol

monooxygenases and formaldehyde oxidation genes, indicating a methane oxidation system that deviates from those known from Type I and II methanotrophs (Dunfield et al., 2007).

Habitats

Although current isolates require high methane partial pressures for growth, some methanotrophs can apparently utilize methane with high affinity at low partial pressures, down to atmospheric levels (Hanson and Hanson, 1996). Therefore, they are ubiquitous in soil and water. Increased populations and activity occur wherever increased methane concentrations, whether from biogenic or other sources, meet oxic conditions. Typical habitats are thus closely tied to sites with methanogenesis (see Chapters *Methane, Origin*; *Methanogens*), e.g., rice paddies, swamps, aquatic and terrestrial sediments, land-fill coverings, and the oxycline of stratified water bodies (Hanson and Hanson, 1996). In stratified systems, (e.g., in stratified water bodies or sediments) aerobic methane oxidation will often be located within a relatively narrow band within the oxycline, where methanotrophs can become highly enriched. Methanotrophs also occur as endosymbionts, e.g., of marine mussels found at cold seeps (qv) that use methane released to supply their hosts with carbon and energy (Hanson and Hanson, 1996; Bowman, 2006).

Methods to study aerobic methane oxidation and methanotrophs

Methane oxidation rates in environmental samples are frequently determined by incubation experiments. Samples are placed in a gas-tight container and the consumption of methane over time is determined in the headspace. Alternatively, ¹⁴C labeled methane can be used to quantify the conversion to CO₂ and incorporation into the bacterial biomass. Field methods include the use of push–pull tests (Urmann et al., 2005), or modeling of rates based on methane gradients.

Methanotrophs can be cultured from almost any environment using a nitrate mineral salts medium and a CH₄/air atmosphere (Madigan et al., 2003; Bowman, 2006). Since they are relatively easily cultured, viable count methods can be used but will severely underestimate the actual population, due to the prevalence of viable but nonculturable cells. Since they are phylogenetically well defined, methanotrophs can be detected and quantified using ribosomal RNA as a genetic marker, e.g., using specific oligonucleotide probes (e.g., for fluorescent in-situ hybridization) or primers for polymerase chain reaction based detection (PCR) (McDonald et al., 2008). In addition, the gene sequences of functional genes, most frequently the gene encoding pMMO (pmoA), but also genes for sMMO (mmoX) and methanol dehydrogenase (mxaF), are frequently used as molecular markers for

PCR-based detection (Hanson and Hanson, 1996; Bowman, 2006; McDonald et al., 2008). A hybridization microarray was developed for rapid phylogenetic typing of PCR amplified *pmoA* (Bodrossy et al., 2003). Type I and II methanotrophs also contain biomarkers (see Chapter *Biomarkers (Organic, Compound-Specific Isotopes)*), e.g., specific lipids and phospholipid fatty acids that are useful in tracing community changes (Hanson and Hanson, 1996; Bowman, 2006; Schubert et al., 2006; Blumenberg et al., 2007).

Geochemical impact

Locally, methanotrophs can be an important basis of the food web, if sufficiently large fluxes of methane are converted to biomass and passed on down the food chain. Since biogenic methane (see Chapters *Methane, Origin; Methanogens*) has a strongly ^{13}C depleted carbon isotope signature, carbon flow originating from oxidized methane can be studied using isotope measurements (see Chapter *Isotopes (Methods)*).

The primary importance of aerobic methane oxidation for the global *carbon cycle* (qv) is that it represents (together with *anaerobic methane oxidation* (qv) and photochemical methane oxidation in the atmosphere) a major sink for this radiatively active and therefore, important greenhouse gas. Globally, photochemical methane oxidation is by far the dominant process (94%), but microbial oxidation is an important factor to take into account when projecting global warming effects. Obtaining global estimates of microbial aerobic methane oxidation is not trivial due to high spatial and temporal variability and the difficulty in performing rate measurements in environments where methanogenesis and methanotrophy occur simultaneously. The total sink function of soils has been estimated at 29 Tg year^{-1} , with an uncertainty range of 7–100 Tg year^{-1} (Smith et al., 2000). In rice paddies, methane oxidation can occur in the rhizosphere and at the soil surface, and is estimated to remove 80% of the methane produced in these systems, but there is uncertainty that CH_4 bypass would possibly occur through vascular plants' parenchyma. Methane oxidation rates in soil depend on various factors, e.g., soil bulk density, water content, temperature, and pH (Hanson and Hanson, 1996). The process is also often limited by the rate of methane diffusion into the oxic zone. Further, ammonium is a competing substrate for MMO that is not coupled to energy generation and therefore acts as a poison to methanotrophs at higher concentrations (Madigan et al., 2003). Thus, the methanotroph activity in soil is subject to considerable variability and sensitive to land use changes, and is one factor to be considered for mitigation strategies to reduce atmospheric methane concentrations (Hanson and Hanson, 1996).

Lakes were long considered a minor source of methane, a view that has somewhat changed based on observation of significant methane fluxes from reservoirs (St. Louis

et al., 2000). In permanently or temporally stratified water bodies such as lakes, reservoirs, or the Black Sea, a large proportion of the methane is oxidized by aerobic methanotrophs in the chemocline (Schubert et al., 2006; Blumenberg et al., 2007).

While the open ocean is not considered a major source of methane, and methane oxidation activity is generally low, *cold seeps* (qv) release large amounts of methane from sediments and hydrocarbon deposits (including *gas hydrates* (qv)), creating high local fluxes of methane (see Chapter *Methane, Origin*). This creates a situation where symbiotic as well as free-living methane oxidizers are the basis of large oceanic food webs. However, in anoxic marine sediments *anaerobic methane oxidation* (qv) coupled to sulfate reduction is the most important process.

Summary

Aerobic oxidation of methane is performed by specific bacteria, the methanotrophs, which use a specific metabolic pathway for carbon assimilation and energy generation from methane. Most known methanotrophs belong to the Proteobacteria, but recent discoveries of novel methanotroph *Verrucomicrobia* indicated that the diversity of methanotrophs is not yet fully known. Aerobic methane oxidation is one of the major sinks for the greenhouse gas methane, along with *anaerobic methane oxidation* (qv) and photochemical oxidation in the atmosphere. It is, thus, an important process for the global *carbon cycle* (qv) and an important element in the regulation of the atmospheric concentration of methane.

Definition

Methane is a colorless and odorless gas, with the chemical formula CH₄. Due to its radiative force, it is a strong greenhouse gas and contributes to the warming of the earth. It is formed in the environment by methanogenesis. The main natural sources are wetlands and termites (30% of total emissions), while anthropogenic sources include rice fields, cattle farming, and energy production (70% of total emissions).

General aspects

Methane is a colorless and odorless gas and the major component (97% vol.) of natural gas. Methane has a boiling point of −161°C at a pressure of one atmosphere. As a gas, it is flammable only over a narrow range of concentrations (5–15%) in air. It is mainly produced by microorganisms (methanogens) under anoxic conditions in a process called methanogenesis. These conditions exist under water-covered soils, such as rice paddies, tundra, swamps, and marshes, but also in freshwater and marine sediments. Other anoxic environments include ruminant stomachs and termite guts (see [Table 1](#)).

Methanogenesis is the final step in the anaerobic degradation of organic carbon, with methane being formed as a waste product. Methanogenesis is performed by strict anaerobes called methanogens, organisms belonging to the Archaea (a domain of life alongside Bacteria and Eukaryota). Methanogens are rather cosmopolitan in respect to environmental conditions (i.e., temperature, pH, salinity; as long as the environment is anoxic) and represent the largest and most diverse group in the Archaea domain (Magonigal et al., 2004; c.f. Boone et al., 1993). Methanogens are able to grow at temperatures between 4°C and 100°C, at pH values from 3 to 9, and at salinities ranging from brines to freshwater. Despite this huge taxonomic diversity, the substrates that can be used by methanogens are rather limited – hydrogen, acetate, formate, some alcohols, and methylated compounds (Zinder, 1993). The most important of these are hydrogen and acetate, which give rise to two different kinds of methanogenesis: (1) the fermentation of acetate to CO₂ and CH₄ and (2) the reduction of CO₂ with H₂.

Garcia et al. (2000) showed that over 70% of methanogens use the latter pathway, which is known as hydrogenotrophic methanogenesis or carbon dioxide/hydrogen reduction. Hydrogen in this reaction is used both as an energy source and electron donor, whereas CO₂ is the electron acceptor and the carbon source. This reaction yields the most energy of all methanogenic processes – much more than acetate fermentation, which yields the least (see [Table 2](#)). Since hydrogen occurs only in very low concentrations in natural environments, it is the limiting substrate in CO₂/H₂ reduction.

Only 10% of the methanogenic genera, i.e., *Methanosarcina* and *Methanosaeta*, are able to use the other pathway, called acetate fermentation or acetoclastic

Methane, Origin, Table 1 Methane properties

Methane properties	
Chemical formula	CH ₄

Boiling point	−161.6°C
Solubility in water	3.5 mg/100 ml

methanogenesis (Garcia et al., 2000). Despite its limited taxonomic distribution, most likely related to the small amount of energy gained from this process (see Table 2), acetate fermentation seems to be the dominant pathway for methane production in the environment.

Isotopic composition

One of the diagnostic features of methane often used in microbiological, geological, and biogeochemical investigations is its carbon and, to a lesser extent, hydrogen isotopic composition. Due to its biogenic or thermogenic formation, the ^{13}C composition is strongly depleted (i.e., more negative values, see Equation 1).

$$\delta^{13}\text{C} = ((^{13}\text{C}/^{12}\text{C} \text{ sample}) / (^{13}\text{C}/^{12}\text{C} \text{ standard}) - 1) \times 1,000 \text{ vs. VPDB} \quad (1)$$

(Vienna Pee Dee Belemnite)

Methane, Origin, Table 2 Reaction and standard changes in Gibbs free energies for methanogenesis (Adapted from Garcia et al., 2000)

Reaction	ΔG° (kJ/mol CH_4)
$4\text{H}_2 + \text{CO}_2 \rightarrow \text{CH}_4 + 2\text{H}_2\text{O}$	-135.6
$4\text{Formate} \rightarrow \text{CH}_4 + 3\text{CO}_2 + 2\text{H}_2\text{O}$	-130.1
$2\text{Ethanol} + \text{CO}_2 \rightarrow \text{CH}_4 + 2\text{Acetate}$	-116.3
$\text{Methanol} + \text{H}_2 \rightarrow \text{CH}_4 + 2\text{H}_2\text{O}$	-112.5
$4\text{Methylamine} + 2\text{H}_2\text{O} \rightarrow 3\text{CH}_4 + \text{CO}_2 + 4\text{NH}_4^+$	-75.0
$4 \text{ 2-Propanol} + \text{CO}_2 \rightarrow \text{CH}_4 + 4\text{Acetone} + 2\text{H}_2\text{O}$	-36.5
$\text{Acetate} \rightarrow \text{CH}_4 + \text{CO}_2$	-31.0

This is related to a kinetic isotope effect where ^{12}C carbon is preferentially used by microorganisms when methane is formed (Whiticar, 1999). This isotopic effect is not as pronounced in the case of methane formed by heating, or with higher pressures during gas formation from a source rock. In Figure 1, mean values of carbon isotopic compositions are shown for various organic and inorganic materials. Whereas carbonates formed in seawater have values around 0‰ VPDB, and atmospheric carbon dioxide shows a global value of around -8‰ VPDB, methane shows highly depleted values between -25‰ and -110‰ VPDB. This significant feature (sometimes in combination with hydrogen isotopes) has been used in numerous studies to reveal, for instance, the origin of methane (Whiticar et al., 1986) or methane oxidation processes in old carbonate rocks, sediments, or water columns of lakes and oceans (Boetius et al., 2000; Peckmann and Thiel, 2004; Schubert et al., 2006). Not only can the formation process (i.e., biological or thermodynamically controlled) be derived, but also changes that occur during its usage and transformation, and therefore the origin/source of methane be determined. Whenever microorganisms use methane as an energy or food source, they preferentially take up the light ^{12}C carbon. This leads to very light carbon isotopic compositions of, for instance, the cellular lipid structure, as can be seen in the process of anaerobic methane oxidation (see Chapter *Anaerobic Oxidation of Methane with Sulfate*). In contrast, the remaining methane will be enriched in ^{13}C , leading to the heavy isotopic values of, for instance, methane in water columns or sediments. Fractionation factors – the relation between the isotopic composition of the original methane and the methane after transformation – provide a tool for quantifying the amount of methane that has reacted.

Methane, Origin, Figure 1 Carbon isotopic composition of various organic and inorganic materials, and recent marine sediments. Note that methane has the widest range of all compounds. Atmospheric methane has a global carbon isotopic value of about -47‰ versus VPDB.

Fractionation factors are also important during methane formation. Whiticar et al. (1986) showed that different microbial formation processes, such as carbon dioxide reduction or fermentation, lead to different isotopic compositions of the methane formed. This is related to the bonds that need to be broken during the methane formation process.

Whereas during acetate fermentation (Equation 2) the methyl group stays intact and therefore only a small overall isotopic fractionation occurs, during hydrogenotrophic methanogenesis (Equation 3) the bond between the oxygen and carbon of the carbon dioxide has to be broken, leading to a much bigger isotope effect.

The $\delta^{13}\text{C}_{\text{CH}_4}$ from different sources/environments covers a fairly wide range due to variations in methanogenic substrates and mechanisms (Tyler, 1991). Additionally, fractionation associated with oxidation leads to a rather wide $\delta^{13}\text{C}$ range. In general, CH_4 from geological or thermogenic sources is isotopically heavier (-30‰ to -50‰ VPDB) than that from biological sources (-40‰ to -80‰ VPDB). Also, the CH_4 produced by decomposition of either C3 or C4 plant material leads to a distinctive isotopic composition, since the original material is formed via different photosynthesis systems known to fractionate carbon in a different way.

Atmospheric methane has a relatively stable carbon isotopic value globally – around -47‰ VPDB (see compilation in Stevens and Wahlen, 2000).

Relevance as a greenhouse gas

Methane is the shortest hydrocarbon and the most abundant organic compound in the atmosphere. Due to its ability to absorb on the infrared band, it is a potent greenhouse gas. Taking into account its residence time in the atmosphere (about 10 years), its concentration, and its specific absorbance wavelength, it is about 23 times more potent as a greenhouse gas than CO_2 (IPCC, 2001).

Methane mixing ratios in the atmosphere have doubled over the last 200 years, increasing by about 1% per year from 1978 and reaching a value of 1.7 ppm in 1990 (Figure 2a). Since then, the yearly increase has slowed down and values of 1.8 ppm are measured today (Figure 2b).

During the past 15 years, the annual growth rate of tropospheric methane has shown striking changes over 2- to 3-year periods, varying from $+1\%$ year $^{-1}$ to slightly negative values (-0.2% year $^{-1}$). These fluctuations are superimposed on an overall slowdown of the CH_4 growth rate since the 1980s. The general reduction in atmospheric methane growth seems to be related not to a change in source strength, but to source stabilization and the methane budget approaching a steady state (Dlugokencky et al., 2003).

Methane sinks

The strongest sink for methane is oxidation by OH radicals in the troposphere (Badr et al., 1992). Approximately, 94% of methane is lost due to oxidation here and in the stratosphere. Due to photochemical reactions, the above-mentioned reaction produces H_2O , CO , and CO_2 , and hence influences concentrations of ozone, hydroxyl radicals, and CO in the troposphere. Another sink term that needs to be taken into account is soils, in which approximately 6% of methane is oxidized by methanotrophic bacteria.

Recently, the focus has been on oxidation processes that take place in aquatic systems. So far, these have not been included in the source/sink budgets, presumably since none of the methane reaches the atmosphere. However, it is mentioned here as it is an important sink that prevents methane from reaching the atmosphere, and therefore from acting as a greenhouse gas. In aquatic systems, two main processes lead to a loss of methane. One is oxidation by methanotrophic bacteria under oxic conditions in the uppermost sediments and overlying water column (see Chapter *Anaerobic Oxidation of Methane with Sulfate*). The other possibility, and probably the major pathway, is oxidation by methanotrophic archaea under anoxic conditions in deeper sediments and water columns lacking oxygen (see Chapter *Anaerobic Oxidation of Methane with Sulfate*). These two main degradation processes largely restrict the emission or ebullition (transport by bubbles) of methane to the atmosphere from aquatic systems. Normally, 95–99% of the methane found in deeper sediments is oxidized either directly in the sediments or later in the water column and does not, therefore, reach the atmosphere.

Methane sources

In general, methane sources can be divided into abiotic (20%) and biogenic sources (80%). Abiotic sources include fossil carbon sources, such as coal mining, industrial waste treatment, and combustion processes (e.g., aircraft and automobile exhausts), as well as sea floor and volcanic emissions. Biomass burning during deforestation and for heating purposes also falls into this category. However, most methane is produced by biological processes: the major sources are freshwater wetlands and rice paddies, but ruminants and the guts of termites are also important contributors.

The total methane budget may also be divided into emissions from natural or anthropogenic sources (Figure 3). The major sources are discussed in detail below. In considering the various contributors, it should always be borne in mind that estimates for individual sources still vary widely, although ongoing research is seeking to constrain the budget (c.f. Table 7.6 in Denman et al., 2007).

Wetlands

Wetlands, covering about $5.3 \times 10^{12} \text{ m}^2$ globally (Matthews and Fung, 1987), are one of the most important

Methane, Origin, Figure 2 Methane mixing ratios over the last 1,000 years (a) and over only the last century (b) (adapted from Khalil, 2000). Data from Rasmussen and Khalil (1984) and Etheridge (1992). It is evident from the data obtained from ice cores that the drastic increase only started 200 years ago. During the last 20 years, a slowdown in methane concentrations in the atmosphere is visible.

natural sources of atmospheric methane, with an estimated contribution of 115 Tg year^{-1} (Cicerone and Oremland, 1988). Peat-rich bogs in the northern hemisphere ($50\text{--}70^\circ\text{N}$) were mentioned in particular, accounting for 60% of total wetland methane emissions, with tropical and subtropical swamps releasing only 25% of the total (Matthews and Fung, 1987; Fung et al., 1991). The rest was attributed to fens, marshes, and floodplains. However, the high level of emissions from northern wetlands (based on only a few methane emission measurements) was later scaled down, using a process-based methane emission model (Cao et al., 1996). In northern wetlands, according to this publication, CH_4 flux rates per square meter are low ($40 \text{ mg CH}_4 \text{ m}^{-2}\text{day}^{-1}$), but the area of wetland is

large. Therefore, northern wetlands and moist/dry tundra together contribute 25% to global emissions. The second term includes temperate wetlands with a higher mean flux rate ($150 \text{ mg CH}_4 \text{ m}^{-2}\text{day}^{-1}$) but a much smaller area, leading to a contribution of 19%. Since tropical wetlands – mainly swamps – have an even higher mean daily flux ($199 \text{ mg CH}_4 \text{ m}^{-2}$), they account for 56% of total wetland emissions despite covering a much smaller area than northern wetlands.

The carbon isotopic composition of methane emitted from wetlands varies from -86‰ to -31‰ VBDP (compilation by Bréas et al., 2001). This rather wide range is, of course, a function of the formation process (methanogenesis by acetate fermentation or CO_2/H_2

Methane, Origin, Figure 3 Net emissions of methane stemming from natural (a) and anthropogenic sources (b). Numbers have been taken from Scenario 7 of Fung et al. (1991). The drastic variations from one study to another are attributable to the wide ranges of emission estimates (for instance, wetland emission estimates vary from 100 to 230 Tg CH₄ year⁻¹), and freshwater emissions (see below) have yet to be accounted for.

reduction), the original degradation material forming the substrate for methanogenesis (C3 or C4 plants), and more or less strong methane oxidation, leaving behind isotopically heavy methane.

Termites

Termites feed on all kinds of food, including wood, grass, leaf litter, and agricultural crops. It is very difficult to estimate the amount of methane produced anaerobically in the guts of termites, since it is highly variable between species and colonies. The total amount, mainly produced in tropical savannahs and forests, is estimated at 20 Tg CH₄ year⁻¹.

The carbon isotopic composition of methane emitted from termites varies from −73‰ to −44‰ VBDP (Tyler et al., 1988). Interestingly, the $\delta^{13}\text{CH}_4$ of termite-emitted methane is independent of diet.

Rice fields

Rice is cultivated either on dry land, from which no methane is emitted, or – in the case of about 80% of global cultivation – on irrigated fields, leading to high methane emissions. Rice is cultivated between 50°N and 50°S on an area of 1.3×10^6 km², mostly situated in Asia (90%) (Bréas et al., 2001).

Globally, methane emissions from rice fields are second to those from wetlands and represent the highest anthropogenic budget term (100 Tg CH₄ year⁻¹). On rice fields, a methane release rate between 0.4 and 0.8 g m⁻² day⁻¹ has been observed (Holzapfel-Pschorn and Seiler, 1986). Methane in rice fields is produced by methanogens which find an ideal environment in flooded soils, i.e., high organic carbon loads and anoxic conditions. The amount of methane produced has been shown to be influenced by several factors, such as soil properties, amount and type of fertilizer, irrigation, etc. The carbon

isotopic composition of methane emitted from rice fields also varies widely due to the same variables as found in wetlands and lies between −50‰ and −68‰ VBDP (compilation in Bréas et al., 2001).

Enteric fermentation in animals

Methane is formed in the rumen of animals as a by-product of carbohydrate chain (e.g., cellulose) degradation. During digestion, ingested macromolecules are broken down into smaller molecules by enzymes. Subsequently, the fermentation of, for example, glucose leads to even smaller molecules, such as acetate, butyrate, H₂ and CO₂, etc. The H₂ produced, together with CO₂, is then immediately used by methanogens to form methane.

Global methane emissions mainly from cattle, buffalo, and sheep range between 65 and 100 Tg CH₄ year⁻¹ (Cicerone and Oremland, 1988) and are therefore comparable to rice cultivation and wetland emissions.

Biomass burning

Whereas the burning of biomass mainly produces CO₂, the subsequent smoldering phase – involving compounds with low combustion efficiency – mainly produces methane. About 85% of methane emissions related to biomass burning stem from tropical areas due to deforestation and fuel wood use. It is estimated that biomass burning accounts for 8–10% (i.e., 40–55 Tg CH₄ year⁻¹) of total methane emissions (Cicerone and Oremland, 1988; Hein et al., 1997).

Mining, gas drilling, natural geological sources

During coal mining and gas drilling, methane is produced not by biological processes but from catagenesis of coal or maturation of petroleum and subsequently released into the atmosphere. Cicerone and Oremland (1988) and

Fung et al. (1991) estimated these emissions to be in the order of $75 \text{ Tg CH}_4 \text{ year}^{-1}$.

Recently, Kvenvolden and Rogers (2005) estimated the amount of methane emitted from natural geological sources, i.e., not related to petroleum production or mining, to be in the order of $45 \text{ Tg CH}_4 \text{ year}^{-1}$. Those geological sources include natural macro- and micro-seeps, mud volcanoes, and other miscellaneous sources such as gas hydrates, magmatic volcanoes, geothermal regions, and mid-ocean ridges.

Landfills

Globally, methane emitted from landfills following the breakdown of organic material via methanogenesis is estimated to contribute about $43 \text{ Tg CH}_4 \text{ year}^{-1}$ (Hein et al., 1997).

Oceanic emissions

Methane production in the ocean is found basically in two different environments: (1) in anoxic microenvironments of surface waters, e.g., in fish intestines, plankton samples, marine snow, and fecal pellets and (2) in anoxic sediments due to the breakdown of organic material. The first of these is also known as the “Ocean Methane Paradox,” since methane production would not be possible normally in oxic ocean water and is therefore restricted to these microenvironments. Although only relatively small amounts of methane are formed by this mechanism, leading to supersaturation of surface waters, the huge area of the oceans is responsible for making this term globally significant. Methane produced in sediments might be released into the water column by diffusion or by methane seeps and vents, or it might be locked up in gas hydrates (see below).

Methane emissions from the various kinds of seeps that occur in the oceans – in shelf regions, slopes, or deep ocean locations – are estimated to be between 1 and $65 \text{ Tg CH}_4 \text{ year}^{-1}$ (see compilation in Judd et al., 2002). The best investigated regions in this respect are the Santa Barbara Basin, where at Coal Oil Point an emission of $28 \text{ g CH}_4 \text{ m}^{-2} \text{ year}^{-1}$ was estimated (Hornafius et al., 1999), and the Black Sea, where more than 2,000 seeps were detected in the area west of the Crimean Peninsula alone. The yearly atmospheric methane contribution from seeps in the Black Sea is estimated to range between 0.03 and 0.15 Tg (Dimitrov, 2002).

Since most of the methane from seeps or sediments is oxidized by either aerobic or anaerobic processes in the sediments or in the water column, total oceanic emissions today are estimated to be in the order of 10 Tg year^{-1} (Cicerone and Oremland, 1988; Fung et al., 1991). It has to be taken into account that for methane released into the water column in the form of bubbles, the contribution to the atmosphere may be much higher, depending on the water depth. However, when bubbles travel through the water column, they exchange methane with the ambient

water; consequently, most of the gas in the bubbles at the water surface is composed of nitrogen rather than methane (McGinnis et al., 2005).

Gas hydrates

Gas hydrates are nonstoichiometric solid structures composed of ice-like minerals that form at low temperatures and high pressures in the deep sea or at low temperatures in permafrost regions. They can be thought of as a hydrogen-bonded water framework called a host lattice that traps guest molecules (typically gases). In general, three types of gas hydrates can be distinguished based on the structure in which they crystallize. These are structure I, structure II, and structure H (which occurs more rarely). Hydrates contain gases such as hydrocarbons (including methane, hydrogen sulfide, and carbon dioxide) that glue themselves inside symmetrical cages of water molecules to form hydrate crystals (mainly found in type I structures). Smaller molecules, such as argon, krypton, and nitrogen, are found in smaller cages related to structure II.

Gas hydrates or clathrates are known to occur mainly on continental margins all over the world at depths of around 600 – 3,000 m, depending on the prevailing temperature gradient (see Figure 4). Since pipelines of offshore drilling platforms are also located in these depths, clogging of pipes due to the formation of gas hydrates is a well-recognized problem.

Gas hydrates are confined to the top few hundred meters of marine sediments. They are stable when the temperature is at or below the value $T_3(P)$ for a three-phase equilibrium between clathrate, liquid water, and methane gas (Buffett and Archer, 2004). Experimental determinations of $T_3(P)$ are shown in Figure 4 as a function of depth, assuming a hydrostatic increase in pressure. Superimposed on this figure is a schematic illustration of the temperature profile through the ocean and sediments. The zone of stability is limited by the intersection of the local temperature profile with $T_3(P)$, although clathrate is confined to the sediments because the concentration of methane in the ocean is too low to form clathrate and, even if it did form, the buoyancy of clathrate in seawater would carry it out of the stability zone. Clathrate is unlikely to form below water depths of less than 600 m (except in the cold Arctic Ocean) because the bottom water is too warm for stability. As the depth of the water increases, and the temperature of the seafloor decreases, the zone of stability becomes thicker and capable of accommodating larger volumes of clathrate.

It must be understood that gas hydrates are by no means stable: these structures dynamically trap methane from, or release methane into, the ocean. This feature led Hovland and Judd (1988) to conclude that slides and craters on ocean shelves might be related to rapid hydrate decomposition.

Going back in time, gas hydrates have even been claimed to be responsible for larger environmental

Methane, Origin, Figure 4 Schematic illustration of temperature through the ocean and uppermost marine sediments (Buffett and Archer, 2004). The temperature for clathrate stability, $T_3(P)$, increases with pressure (or depth). Experimental data for $T_3(P)$ in pure water (dashed line) and seawater (solid line) are extrapolated using a thermodynamic model (Sloan, 1998). The base of the stability zone is defined by the intersection of the geotherm with $T_3(P)$.

catastrophes. Based on light carbon isotopic excursions in the late Paleocene (50 million years ago), Dickens et al. (1995) suggested that methane from gas hydrates might have been released into the atmosphere, leading to significant warming (4°C) during that time.

One of the main features used to find gas hydrates on ocean margins today is the bottom-simulating reflector, which shows up using seismological methods. This is formed by the base of solid gas hydrate and free gas accumulating below in the sediments.

It has been estimated that the amount of carbon (and therefore, energy) stored in gas hydrates (10,000 Gt C) is at least twice as great as in all known oil, gas, and coal fields combined (Kvenvolden and Lorenson, 2001). This would be equal to 2,000 times the atmospheric methane inventory. However, recent estimates have brought the abundance of gas hydrates down from 1×10^{17} – 10^{18} m^3 to $(1\text{--}5) \times 10^{15} \text{ m}^3$, also reducing the energy stored in gas hydrates globally to 500–2,500 Gt C (Milkov et al., 2004). Buffett and Archer (2004) estimated that about 3,000 Gt C occurs in clathrate and 1,800 Gt C in methane bubbles. Estimates of the amount

of gas hydrate-related methane actually emitted into the atmosphere reach $5 \text{ Tg CH}_4 \text{ year}^{-1}$ (Wuebbles and Hayhoe, 2002).

Freshwater emissions

Recently, freshwater environments, including lakes and reservoirs for hydropower production, have become the focus of attention not only for CO_2 , but also for methane emissions. Lakes kept in a natural state or with only minor influence by humans undergo normal aerobic degradation of organic material and mainly emit CO_2 . However, when organic material production is high, natural lakes also turn anoxic either in the water column or in the sediments and release methane due to anaerobic degradation, i.e., methanogenesis. This occurs even more rapidly in systems that are highly eutrophicated, e.g., due to intensive agriculture or effluents from sewage treatment plants.

In contrast, reservoirs are normally man-made. By damming rivers, huge areas are flooded and the water is stored for energy production. If the flooded area is a forest, peatland, or grassland, then – instead of being a sink for CO_2 due to photosynthesis – this area will become a source of greenhouse gases due to anaerobic decomposition of the submerged organic material. For example, in the boreal region of Canada, flooded peatlands represent a worst-case scenario, since they possess a large store of organic carbon held in peat, which can decompose and return to the atmosphere as greenhouse gases over a long period (Kelly et al., 1997). It makes a difference to the emission rate whether an area has only been flooded recently or was flooded decades ago. A newly formed reservoir will emit methane at a much higher rate, since fresh organic material is rapidly degraded. In contrast, reservoirs which are already tens of years old show lower methane emissions, since the older and more refractory organic material is harder to degrade.

Due to recent plans to trade or tax carbon dioxide emissions, “green” hydropower is under debate and it is therefore necessary to define the related CO_2 and methane emissions.

In a compilation (Table 1 in St. Louis et al., 2000), methane fluxes from temperate reservoirs varied from 1 to $260 \text{ mg m}^{-2} \text{ day}^{-1}$. Tropical reservoirs showed even higher fluxes, evolving from higher productivities, of $2\text{--}3,800 \text{ mg m}^{-2} \text{ day}^{-1}$ (St. Louis et al., 2000). Average fluxes were $20 \text{ mg m}^{-2} \text{ day}^{-1} \text{ CH}_4$ for temperate and $300 \text{ mg m}^{-2} \text{ day}^{-1} \text{ CH}_4$ for tropical reservoirs. Taking an area of $0.9 \times 10^6 \text{ km}^2$ for temperate and $0.6 \times 10^6 \text{ km}^2$ for tropical reservoirs, a global flux of 70 Tg can be estimated (St. Louis et al., 2000).

Emissions from natural lake systems have been recently evaluated by Bastviken et al. (2004). In these systems, three different pathways for methane emission are described: (1) ebullition, i.e., emission through bubbles, (2) diffusive flux, which mainly depends on surface methane concentrations and wind speed over surface waters, and (3) storage, i.e., methane released during lake

turnover. On average, these various pathways contribute 62%, 31%, and 7% to total emissions, respectively.

Using different regression equations for surface CH₄ concentrations, ebullition, diffusive flux, and storage, together with data on lake area and lake numbers (Kalf, 2002), Bastviken et al. (2004) estimated methane emissions from lakes on a global basis. When compared to global nonanthropogenic emission values from Wuebbles and Hayhoe (2002), the estimated lake emissions of 8–48 Tg CH₄ year⁻¹ represent 6–16% or 2–10% of total emissions.

Taking the two systems (natural lakes and reservoirs) together results in global methane emissions between 78 and 118 Tg year⁻¹. These figures are similar to emissions from wetlands, the largest natural contributor, and much higher than estimated oceanic emissions. Although these estimates might be on the high side, they clearly show that emissions from freshwaters have to be included in global methane budgets.

Summary

Methane is the end product of organic matter degradation under anoxic conditions. In freshwater environments methanogenesis is the main pathway due to the low sulfate concentrations, whereas in the marine environment methanogenesis becomes important only after sulfate, as an electron acceptor, has been used up completely. Methane is formed by microorganisms belonging to the Archaea known as methanogens. Methanogens are able to grow at temperatures between 4°C and 100°C, at pH values from 3 to 9, and at salinities ranging from brines to freshwater. Despite this huge taxonomic diversity, the substrates that can be used by methanogens are rather limited – hydrogen, acetate, formate, some alcohols, and methylated compounds. The two main pathways described in nature are hydrogenotrophic methanogenesis (also known as carbon dioxide/hydrogen reduction) which is mainly found in marine environments and acetate fermentation (acetoclastic methanogenesis) which is more dominant in freshwater environments. These two processes can be distinguished from each other by measurements of the carbon or hydrogen isotopic composition of the formed methane, since the fractionation factors between substrate (CO₂ or acetate) and methane vary.

Methane is a potent greenhouse gas, ranking second after carbon dioxide as a contributor to global warming. Its concentration has doubled over the past 200 years, although the increase has slowed down over the past 20 years which is thought to be related to source stabilization and the methane budget approaching a steady state.

The main sources of natural emissions are wetlands, termites, and aquatic systems, making up 30% of total global emissions, while the main anthropogenic sources, such as rice paddies, ruminants, energy production, and landfills, account for 70%. Gas hydrates occurring on continental slopes and permafrost regions also store high

amounts of methane; however, most of this methane is oxidized to carbon dioxide before it reaches the atmosphere. Recently, lakes and especially reservoirs have been identified to be major contributors to the global methane budget questioning of hydropower as a “green energy” source.

The main sinks for methane are oxidation with OH in the troposphere (accounting for more than 90%), loss in the stratosphere, and oxidation by methanotrophs in soils.

Microbial biomineral formation

Definition

Microbial biomineralization describes the formation and deposition of minerals directly mediated or indirectly influenced by microorganisms (Mann, 2001; Weiner and Dove, 2003; Ehrlich, 1999). A huge variety of minerals results from individual biomineralization pathways linked to the phylogeny and metabolic activity of the microorganisms involved (Weiner and Dove, 2003;

Minsky et al., 2002). Moreover, microbial biominerals may differ distinctly from their inorganically formed equivalents in shape, size, crystallinity, isotopic, and trace element composition (Bazylinski et al., 2007; Haferburg and Kothe, 2007; Takahashi et al., 2007; Weiner and Dove, 2003). A compilation of microbial biominerals and their source organisms is given in Table 1.

Two principal modes of microbial biomineralization processes occur, namely biologically induced mineralization (BIM) and biologically controlled mineralization

(BCM, Lowenstam, 1981; Lowenstam and Weiner, 1989). These modes are introduced in the following.

Biologically induced mineralization (BIM)

In BIM, the nucleation and growth of biominerals are extracellular processes triggered by the metabolic activity of the microorganism. Biomineralization takes place because of the changes in the chemical equilibrium of the surrounding environment and may also be linked to

Microbial Biomineralization, Table 1 (Continued)

Chemical formula	Mineral name	Involved microorganism	References
Au ⁰	Elemental gold	<i>Bacillus</i> sp., <i>Rhodopseudomonas capsulate</i> , <i>Shewanella algae</i> , SRB	Reith et al. (2009), He et al. (2007), Konishi et al. (2007), Konishi et al. (2006), and Lengke and Southam (2006)
CaCO ₃	Calcite	Communities of SRB and archaea, cyanobacteria, soil bacteria (<i>Bacillus megaterium</i>), Algae (e.g., <i>Halimeda</i> , <i>Emiliana huxleyi</i>)	Boetius et al. (2000), Reitner et al. (2005), Thompson and Ferris (1990), Lian et al. (2006), and de Vrind-de Jong and de Vrind (1997)
	Aragonite	Cyanobacteria (<i>Synechococcus leopoliensis</i>), <i>Nesterenkonia halobia</i> , <i>Halomonas eurihalina</i>	Obst et al. (2009) and Rivadeneyra et al. (1998, 2000)
	Vaterite	<i>Kocuria</i> , <i>Myxococcus Xanthus</i> , <i>Bacillus sphaericus</i>	Zamarreño et al. (2009), and Rodriguez-Navarro et al. (2007)
CaMg(CO ₃) ₂	Dolomite	<i>Nesterenkonia halobia</i>	Rivadeneyra et al. (2000)
SiO ₂ • nH ₂ O	Amorphous silica	<i>Calothrix</i> , <i>Fischerella</i> sp., <i>Shewanella oneidensis</i>	Benning et al. (2004), Konhauser et al. (2001), and Furukawa and O'Reilly (2007)
SiO ₂	Silica	Diatoms, radiolarians, <i>Thiobacillus</i> , <i>Bacillus subtilis</i>	de Vrind-de Jong and de Vrind (1997), Fortin and Beveridge (1997), and Urrutia and Beveridge (1993)
Ca ₅ (PO ₄) ₃ (OH)	Hydroxyapatite/ calcium phosphate	<i>Ramlibacter tataouinensis</i> , <i>Corynebacterium matruchotii</i> , <i>Streptococcus mutans</i> , <i>Streptococcus sanguis</i>	Benzerara et al. (2004), Van Dijk et al. (1998), and Streckfuss et al. (1974)
MgNH ₄ PO ₄ • 6H ₂ O	Struvite	<i>Myxococcus xanthus</i> , <i>Pseudomonas</i> , <i>Flavobacterium</i> , <i>Acinetobacter</i> , <i>Yersinia</i> , <i>Corynebacterium</i> , <i>Azotobacter</i>	Da Silva et al. (2000) and Rivadeneyra et al. (1983)

For comprehensive reading, the following books are recommended: Sigel et al. (2008), Baeuerlein (2000), Banfield and Nealson (1997), Dove et al. (2003), Driessens and Verbeeck (1990), Lovely (2000), Lowenstam and Weiner (1989).

particular metabolic products. The resulting biominerals typically show a poor crystallinity, are chemically heterogeneous, and often closely associated with the cell wall (Frankel and Bazylinski, 2003). An active and a passive mineralization process can be distinguished (Fortin and Beveridge, 2000; Southam, 2000). Active mineralization refers to mineralization by (a) the direct redox conversion of specific metal ions bound to the bacterial surface or (b) the excretion of metabolically produced ions and thereby forming minerals. The term passive mineralization is used when *nonspecific* binding of cations and the involvement of surrounding anions causes nucleation and growth of minerals. Passive mineralization can even be mediated by dead cells, due to the exposure of negatively charged surfaces acting as nucleation sites for metal cations (Urrutia and Beveridge, 1993). Particularly in BIM, extracellular polymeric substances (EPS) are involved in the mineralization process (Chan et al., 2009; Ercole et al., 2007). As an example of BIM, the precipitation of iron oxyhydroxides by the iron oxidizing bacterium *Gallionella ferruginea* is displayed in Figure 1.

Biologically controlled mineralization (BCM)

BCM implies that the organism actively controls the nucleation site, growth, morphology, and final location of the mineral (Banfield and Nealson 1997; Bazylinski

Microbial Biomineralization, Figure 1 Stalk-shaped extracellular polymeric substances (EPS) produced by the iron oxidizing bacterium *Gallionella ferruginea* are heavily encrusted with iron oxyhydroxide minerals formed by biologically induced mineralization (BIM).

and Frankel, 2003). Although the modes of exerting crystallochemical control over the mineralization process may greatly vary across species, the common characteristic of BCM is that mineral formation takes place in a closed, isolated environment. While Weiner and Dove (2003) categorized BCM in *extra*-, *inter*- or *intracellular* mineralization, Mann (2001) differentiated between two key modes of BCM, namely *matrix-mediated* mineralization and *boundary-organized* mineralization. Generally speaking, extracellular mineralization corresponds to matrix-mediated mineralization, whereas inter- and intracellular mineral formation are equivalent to boundary-organized mineralization.

Extracellular BCM implies the production of a macromolecular matrix outside the cell. This matrix is typically composed of proteins, polysaccharides, or glycoproteins, forming a three dimensional framework, and the cell actively supplies cations to the matrix for an “on-site” nucleation and growth of the biomineral (Weiner and Dove, 2003).

Intercellular BCM occurs mostly in single-celled organisms, existing in a community. This type of mineral formation is not common in bacteria, but is commonly found in calcareous algae, for example, *Halimeda* (de Vrind-de Jong and de Vrind, 1997; Borowitzka, 1982).

Intracellular BCM takes place inside specific compartments within the cell, for instance vesicles or vacuoles. Thus, the organism is able to exactly regulate the chemical composition, morphological structure, and particle size of the mineral. The only bacteria known to perform intracellular BCM are magnetotactic bacteria, which use a vacuole-based system for the crystallization of magnetic biominerals (Table 1). Similar systems of intracellular

Microbial Biomineralization, Figure 2 Intracellular iron sulfide (greigite, Fe_3S_4) crystals formed by biologically controlled mineralization (BCM) within a magnetotactic bacterium. (Image courtesy of Joachim Reitner.)

BCM are only known from higher eukaryotic organisms, controlling for example, the bone and teeth formation in mammals (Kirschvink and Hagadorn, 2000). An example of microbial biominerals formed by intracellular BCM is shown in Figure 2.

MICROBIAL COMMUNITIES, STRUCTURE, AND FUNCTION

Michael W. Friedrich
 University of Bremen, Bremen, Germany

Definition

Microbial species. Microorganisms exhibiting a high degree of phenotypic and genetic similarity; a pragmatic approach to demarcating “microbial species” using molecular biology tools has been 97% 16S rRNA sequence identity or 70% genome identity based on DNA-DNA hybridization (Stackebrandt and Goebel, 1994); thus, microbial species are often defined by operational characteristics (operational taxonomic unit). The microbial species concept is still a matter of controversy.

Microbial population. Individual microorganisms (of the same “species”) form a population.

Guild. Metabolically related populations, e.g., sulfate-reducing microorganisms.

Microbial community. All microbial populations in a habitat.

Microbial community structure. The composition of a microbial community and the abundance of its members.

Microbial diversity. The number of different species in a habitat; sometimes (falsely) used as a synonym for community structure.

Habitat. The physical location or dwelling place of a particular organism, where an individual microbial ecotype can be found or isolated from.

Ecosystem. A community of microorganisms and their natural environment.

Ecological niche. Different from the habitat (spatial), the niche defines the function of an organism.

Introduction

Microorganisms are an indispensable part of the biogeochemical cycles on Earth, have the longest history in evolution, and represent the largest genetic reservoir. Mostly invisible to the naked eye, microbes represent the largest source of biomass on Earth, with an estimated number of $4\text{--}6 \times 10^{30}$ cells, and 350–550 Pg of C (1 Pg = 10^{15} g), and have colonized almost any niche available on Earth (Whitman et al., 1998). In their habitats, microorganisms usually do not exist as single, genetically identical population, but live together with other microbial populations as microbial communities carrying out important functions of an ecosystem such as primary production and remineralization of biomass.

A hallmark of microbial life is its diversity. For a long time, only little was known about the magnitude of microbial diversity, as this was based on cultivation. Only about ~7,000 noneukaryotic species have been formally described (Euzéby, 1997) (<http://www.bacterio.cict.fr/number.html>), and insects were regarded as much more diverse than microorganisms. In microbiology, the term “diversity” is often used to refer to the number of different species in a given habitat, or, when based on molecular data, refers to the number of different sequences present. Diversity reflects the types of microbes present in a habitat, but “community structure” encompasses quantitative information on the different taxa and guilds (Liesack et al., 1997). Eventually, the analysis of community structure will allow for assessing the role and importance of microbes in their habitats and ecosystems. Presently, it is still methodologically difficult to obtain a complete view of microbial diversity and community structure.

Methods of community structure analysis

Cultivation: Traditionally, the diversity of microbial communities has been studied by cultivation, i.e., by viable plate counts or most-probable-number (MPN) dilution techniques. However, the morphology of microorganisms is too simple for reliable identification and classification. Identification of microorganisms by cultivation requires pure cultures for testing physiological, biochemical, and cell biological characterization and suitable media for their growth, which is a major bottle neck. There are no cultivation media available that allow for capturing growth requirements of all microorganisms in a sample, and we often do not even know of their existence and presence. Direct microscopic counts can be of orders of magnitude higher than the counts of bacteria obtained on growth media (“plate counts”). Typically, only a small

fraction of microorganisms grows on standard media, and in some environments this has been estimated to be as low as 0.001–0.1%, e.g., in seawater (Amann et al., 1995).

Molecular approaches: The limitations of cultivation-based analysis to describe the diversity of microorganisms adequately were overcome by applying methods of molecular biology. Today, microorganisms are routinely classified by using the RNA of the small ribosomal subunit (small subunit ribosomal RNA – SSU rRNA), or its coding gene (SSU rRNA gene) as a molecular marker. In the 1970s, Carl Woese and coworkers used the sequences of the SSU rRNA to establish a phylogenetic framework for all life, from which the concept of the three domains of life – prokaryotes, archaea, and eukaryotes – emerged (Woese and Fox, 1977; Woese, 1987). Molecular classification of microorganisms was further developed by Norman Pace and his group to cultivation independent analysis of microbial communities in environmental samples by cloning the 16S rRNA gene directly from biomass (Pace et al., 1986). The basic idea is simple: rRNA sequences can be used as identifiers of microorganisms even if they were previously unknown; the sequence allows to establish an evolutionary relationship to other sequences of microorganisms in the databases. Directly extracting DNA from biomass, followed by cloning and sequencing of the (SSU rRNA) sequences of interest, facilitates to examine any environmental habitat. In August 2010, 418,497 16S rRNA sequences were held in the dedicated database Ribosomal database project II (RDP; <http://rdp.cme.msu.edu/>), indicating how successful this approach has been. As the number of different microbial species can be very high in certain habitats, computational approaches have been developed to estimate diversity coverage of clone libraries (e.g., DOTUR) (Schloss and Handelsman, 2005). Cloning and sequencing approaches give an overview of microbial species diversity, but this approach is PCR based and therefore, may not adequately reflect the abundance of community members (von Wintzingerode et al., 1997). Analysis of community structure requires quantification of individual groups of microorganisms. Quantitative dot blot hybridization and fluorescent in situ hybridization (see Chapter *Fluorescence In Situ Hybridization (FISH)*), techniques are being used to determine abundance of uncultured prokaryotes using oligonucleotide probes directed against the SSU rRNA (Amann et al., 1995). Specific probes have been designed using SSU rRNA sequences obtained from the habitat studied and public databases; probeBase is an extensive repository of published rRNA-targeting oligonucleotide probe sequences available to the public (<http://www.microbial-ecology.de/probebase/>).

How diverse is diversity?

Microbial diversity in natural environments: By applying molecular techniques such as DNA reassociation kinetics, it was estimated that 30 g of soil might contain approximately 4,000 different microbial genomes, possibly

representing as many as 13,000 different microbial species (Torsvik et al., 1990). Ever since, soils have been regarded as one of the habitats with the most diverse microbial communities; however, a recent comparative study suggests a higher phylogenetic diversity in sediments possibly linked to salinity as major determinant (Lozupone and Knight, 2007). Estimates from PCR-based 16S rRNA gene sequencing suggested up to 100,000 species per gram of soil (Schloss and Handelsman, 2006). However, these estimates were based on relatively low numbers of sequences (up to 1,000). A new DNA sequencing technology, massively parallel pyrosequencing (Margulies et al., 2005), has allowed to sample as many as 53,000 16S rRNA sequences from one soil sample (Roesch et al., 2007); estimates of diversity based on these sequences suggested that the number of unique sequences never exceeded 52,000.

Function of microbial communities

Ecosystems are individually functioning units including primary producers, consumers, and mineralizing organisms. Microbial communities are the most numerous organisms in any ecosystem, and they control the annual primary production including the recycling of carbon, sulfur, nitrogen, and iron. In a lake ecosystem for instance, photic zone, water column, and sediment harbor functionally different microbial communities. Light energy drives the primary production in the photic zone by a community of phototrophic microorganisms. Photosynthetically fixed carbon and carbon from other sources move through the ecosystem and fuel the community of pelagic chemoorganotrophic aerobes (or anaerobes) in the water column. Eventually, part of the carbon sinks down to the sediment, where a specifically adapted community consisting of several guilds of microorganisms degrades the organic matter in a concerted interdependent manner, resulting in the flow of carbon through the anaerobic microbial food chain (see Chapter *Carbon (Organic, Degradation)*). Several different guilds are involved in the degradation of polymers including polymer hydrolyzing, fermenting bacteria, fatty acid fermenting syntrophs, homoacetogens, and methanogens (Schink and Stams, 2006). As oxygen diffusion into the sediment is severely limited, often microoxic to anoxic conditions occur within a few millimeters depth of the sediment surface because of microbial respiration activity in the very top layer. Concomitantly, anaerobically respiring microorganisms oxidize carbon compounds and transfer electrons to inorganic electron acceptors such as nitrogen oxides, manganese oxides, ferric iron, and sulfate in a sequence that reflects the thermodynamic theory in many environments (Conrad, 1996). Once these electron acceptors are depleted, methanogenesis becomes the terminal electron accepting process, which is typically found in freshwater sediments rich in organic matter, in swamps, or in flooded soils such as rice paddies (Schink and Stams, 2006). The function of the major guilds involved in these processes is known in

principle, mainly because representative microorganisms have been identified by enrichment and isolation techniques. The numerical importance as well as the actual physiological function of such guild representatives in the vast diversity of habitats are still elusive. Although 16S rRNA-based surveys with varying degrees of diversity sampling depths exist for a large number of habitats, mostly, sequences and derived phylogenetic identity alone do not reveal the physiological role these microorganisms have. The SSU rRNA is a very valuable phylogenetic marker, however, most guilds are not monophyletic, i.e., not all microorganisms falling into a coherent phylogenetic cluster have the same physiology. For example, within the Proteobacteria phototrophy is widespread, and thus, a close relative of a phototroph can be a nonphototrophic microorganism. Assignment of physiological characteristics based on close SSU rRNA relationship requires careful evaluation and often is not possible at all. The use of marker genes coding for key enzymes has allowed to target phylogenetically diverse but physiologically coherent guilds of microorganisms (Teske et al., 2003). For example, anaerobic respiratory processes carried out by methanogenic archaea (Friedrich, 2005) or sulphate-reducing (Wagner et al., 2005) prokaryotes can be traced in the environment by targeting the respective key genes.

Linking identity and function to microbial populations

Our understanding of microbial community functioning, mostly, is of principal nature for many ecosystems. Even for numerically abundant microbial species identified by molecular techniques, their ecophysiology and role in ecosystem functioning remain elusive. A major goal in current microbial ecology research is therefore to understand what uncultured microorganisms do in their habitats. What are their metabolic properties, and which microbial species are responsible for defined processes in their habitat?

An elegant concept for the elucidation of the ecophysiology of uncultivated microorganisms relies on the incorporation of isotopically labeled substrates into biomass and the subsequent identification of the microorganisms actively incorporating the label. This approach enables to link metabolic activity to active microorganisms by measuring label incorporation into biomarkers or even whole cells.

Microautoradiography in combination with FISH (MAR-FISH) can visualize cells actively incorporating radioactively labeled substrates in their natural habitats permitted that samples are suitable for FISH (Lee et al., 1999). Alternatively, oligonucleotide probe array technology detects radiolabel incorporation into rRNA extracted from environmental samples (Adamczyk et al., 2003).

The use of stable isotopes (^{13}C , ^{15}N , ^{18}O) for labeling active microbial populations has led to a whole suite of approaches that rely on tracing the incorporation of

labeled substrates into cell components such as lipids (Boschker et al., 1998), DNA (Radajewski et al., 2000), RNA (Manefield et al., 2002), or even whole cells (Lechene et al., 2006). Tracing ^{13}C incorporation into lipids is highly sensitive; however, phospholipids lack phylogenetic resolution and require pure cultures for assigning individual lipids to species. Stable isotope probing (SIP) of nucleic acids represents a direct way to identify microbial populations active in a defined metabolic process. SIP is based on the incorporation of labeled substrate into the cellular biomarker nucleic acids, separation of labeled nucleic acids from unlabeled nucleic acids by density gradient centrifugation, and molecular identification of active populations carrying labeled DNA or RNA. By now, SIP has been used to identify the active players involved in carbon and nitrogen cycling, as well in bioremediation in a large variety of different habitats and has been extended even to metagenomic analysis of labeled DNA (for a recent overview see (Neufeld et al., 2007)).

Whereas the original SIP is based on physical separation of labeled nucleic acid from unlabeled nucleic acid, newer approaches target single cells. Raman confocal microscopy detects shifts in vibrational energy of chemical bonds induced by ^{13}C labeling of cellular of single microbial cells. In combination with FISH, Raman microscopy enables identification of ^{13}C label incorporating active cells (Huang et al., 2007). A conceptually similar approach uses secondary ion mass spectrometry (SIMS) operating at lateral resolution of now down to 33 nm. NanoSIMS has high sensitivity allowing to detect shifts in isotopic signals at per mill rather than the atomic percent range (standard SIP and Raman SIP) and high isotope measurement precision (Lechene et al., 2006). Recently, it has been demonstrated that NanoSIMS analyses can be combined with 16S rRNA targeting oligonucleotide probes by employing halogen atoms as element label allowing in parallel phylogenetic identification and detection of metabolic activity of individual cells (Li et al., 2008).

Conclusions

Molecular biology based approaches have advanced our understanding of microbial diversity enormously over the last 20 years. However, we are just at the beginning of a new era in surveying microbial diversity: we will be witnessing the rapid accumulation of staggering amounts of sequence data not only for the single phylogenetic marker 16S rRNA, but also for whole metagenomes fueled by parallel DNA sequencing technology. New developments in linking phylogenetic identity to function, including renewed efforts in cultivation, will boost our understanding of the ecophysiology of the uncultivated vast majority of microorganisms. Eventually, this ongoing revolution of microbial ecology will allow to test general ecological theory using microbial systems (Prosser et al., 2007).

Synonyms

Mineralization; Nutrient cycling

Definition

Microbial. Processes driven by microorganisms.

Degradation. Use of chemical substances as carbon and energy source for metabolism, thereby breaking down larger molecules to smaller ones.

Introduction

Microorganisms are the basis for the process of mineralization by utilizing organic molecules for their catabolism, thereby returning the elements to the geobiological cycles. In catabolism, or energy conservation, energy-rich adenosine triphosphate (ATP) is formed (for general reading on microbial physiology: Madigan and Martinko, 2006). This is the basis for metabolic degradation performed by microorganisms in a great diversity. The degradation of organic material in terrestrial, limnological, and marine environments is thus based on the growth of microorganisms on organic compounds, which is termed chemoheterotrophic growth style, depending on the availability of organic nutrients for growth. The processes can be dependent on aerobic respiration, but many degradative processes, e.g., in sediments, are performed in the absence of oxygen under anaerobic conditions (Schink, 2002).

Aerobic and anaerobic respiration

The respiration with oxygen as the terminal electron acceptor is the process yielding the most ATP per mol substance oxidized and thus, aerobic respiration is the preferred route for degradation whenever enough oxygen is available. Under aerobic conditions, the degradation of organic matter is performed following general and ubiquitous pathways such as glycolysis; the pyruvate produced in the glycolytic chain enters the citrate cycle; and the reduction equivalents produced are then reoxidized by the respiratory chain coupled to the reduction of oxygen to water. All building blocks of living cells can be degraded that way, allowing growth of microorganisms. The carbon moieties are released as CO₂ into the atmosphere.

Under anaerobic conditions, anaerobic respiratory chains using alternative electron acceptors can ensue. For example, nitrate, nitrite, sulfate, sulfite, sulfur, iron, manganese or fumarate, or carbon dioxide in methanogenesis is then used to accept the electrons, thereby reducing these substances. Halogenated compounds can serve as electron acceptors in dehalorespiration.

All these respiratory chains depend on membrane-bound electron transport, and the reactions of electron transport are coupled to proton export across the cellular membrane to form a proton motive force. The proton motive force is then used to drive ATP formation *via* the enzyme ATP synthase, which can form 1 mol of ATP per 3 mol of protons carried back into the cytoplasm. The electrons for electron transport chains are derived from oxidation of the organic molecules of the nutrient source. If possible, the organic matter is fully oxidized to carbon dioxide. In this way, the organic matter is fully decomposed.

Fermentation

Another route, independent of respiratory chains, is possible for the fermentative degradation of organic matter. The fermentations performed by microorganisms can use oxidation of substrates to produce ATP and then reduce organic molecules for reoxidation of the reducing equivalents. While ATP yield in these systems is limited when compared to respiration, it still allows growth under conditions when no inorganic electron acceptor is available in sufficient amounts, or when iron as part of the electron carriers in the respiratory chain is not available and therefore, an electron transport chain cannot be synthesized.

In contrast to respiration, both aerobic and anaerobic, during fermentation the organic substrate is not fully oxidized to CO₂. Rather, energy conservation is dependent on the oxidation of an organic molecule in which an aldehyde may be formed as intermediate, which subsequently can be oxidized to form an acid. This exergonic reaction is coupled to the activation of an inorganic phosphate moiety which then can be transferred to ADP, thereby forming ATP. This process is called substrate-level phosphorylation in contrast to the electron transport phosphorylation occurring in respiratory chains. The oxidative reaction releases reduction equivalents, which cannot be transferred to an inorganic electron acceptor due to the lack of respiratory chains in fermenting microbes. Thus, the reduction of an organic compound is necessary to release the carrier for a new cycle of oxidation. The reduced organic substance is released into the environment. An alternative is to release the reduction equivalents as H₂.

The fermentation of sugars, which are present in large amounts due to photosynthesis products and constituents of plant cell wall material, can be performed using the Embden–Meyerhof pathway of glycolysis, the Entner–Doudoroff pathway, or modifications or parts thereof. Sugars with 5 C moieties, sugar acids, or carbonic acids can be converted by different pathways. Examples for sugar fermentation are homo- or hetero-fermentative lactic acid fermentation, alcoholic fermentation, propionate fermentation, butyrate or butanole fermentation, mixed acid fermentation, solvent fermentation, and many others. The names of the pathways indicate the products released in these different fermentative pathways.

Many bacteria can switch between fermentative and respiratory metabolism, depending on the availability of

electron acceptors for respiratory chains. If they can switch between anaerobic and aerobic metabolism, they are called facultative aerobes, while anaerobes are usually oxygen sensitive and grow exclusively under anaerobic conditions. Within this group, the Gram-positive *Clostridia* have evolved many fermentation pathways including those to degrade fatty acids, lipids, amino acids and proteins, or nucleic acids under anaerobic conditions. Thus, degradation of all constituents of the cytosol of living organisms under anaerobic conditions can be achieved.

As no oxygen is necessary for the fermentative metabolism, most fermentations will proceed under anoxic conditions. However, aerotolerant microorganisms such as some lactic acid bacteria that are active in decomposition of plant litter can perform this reaction also under oxic conditions, although these anaerobes do not use oxygen as electron acceptor.

Syntrophic degradation

The reduced compounds released by fermenting microorganisms constitute good nutritional sources for organisms that can use respiratory systems. In turn, the use of the product will allow for the continuous production of this compound, as no restrictions for the fermenting bacteria will inhibit their metabolism. The concomitant occurrence of bacteria in an ecological niche in which both partners are dependent on each other and degradation of the substrate is only possible when both partners are present is termed syntrophy.

The basis is the metabolic activity of one organism which forms a substrate for the other. This constant removal of a metabolic end product is exemplified by the release of H_2 which is often a link in such syntrophic systems. Use of hydrogen by a second organism allows the first organism to constantly produce this compound. In pure culture, the partial pressure of H_2 reaches levels inhibitory to the metabolism of the producing organism which subsequently ceases growth. Since the syntrophic partner constantly removes hydrogen, no cessation of growth is observed due to product inhibition in this coculture. This syntrophy, depending on hydrogen transfer between two microbes present in the same environment, is of special importance, and the term interspecies hydrogen transfer has been coined for this syntrophic relationship. However, many different examples can be given for such syntrophic associations of microorganisms (e.g., Ueda and Beppu, 2007). Degradation of recalcitrant substrates, including, e.g., halogenated compounds, is often seen in syntrophic associations.

Cometabolic degradation

Recalcitrant substrates are not, or very slowly, degraded because their conversion is not easily or not at all coupled with energy conservation. Thus, the degradation of these compounds is costly for the cell, and the microorganisms do not profit directly from degradation. Instead, the

bacteria have to use energy from a different, catabolic reaction to drive the unfavorable degradation process.

An example of immediate importance is lignin degradation, which is performed by white rot fungi. The brown rot fungi degrade lignin mainly in order to get access to the cellulose of plant cell wall which is a good nutrient source but not directly accessible in wood and timber. The recalcitrant nature of lignin is seen under anoxic conditions, where the degradation is not possible and lignin of plant origin is thus the basis for coal formation.

As cometabolic systems are costly, they are mostly linked to respiration. Degradation of plant alkaloids, which are also recalcitrant substrates, often occurs at higher rates in oxic conditions.

Degradation of plant litter and soil formation

Plant material is composed of the contents of the living cells and the cell wall materials. Within the cell, secondary plant metabolites are stored in the vacuole. Upon leaf fall or death of a plant, especially the secondary metabolites and the wall materials persist, while proteins and lipids are easily degradable in the unsaturated oxygen containing upper soil layers.

Plant cell walls are composed of cellulose, hemicellulose, pectin, polygalacturonans, and lignin. Even in herbaceous plants, a quarter of the secondary cell wall is lignin. This macromolecule can be degraded aerobically, while anoxic conditions lead to the formation of coal, since under these conditions lignin cannot be degraded. Wood rotting fungi, both brown rot and white rot fungi, are able to degrade lignin (Crawford, 1981). The enzymes involved in lignin degradation, peroxidases and laccases, are able to attack the bonds in the macromolecule linking the phenolic monomers to form the high molecular weight lignin. The monomers can then be degraded further and are metabolized to carbon dioxide. These processes have been studied in some detail at the molecular level (Gold and Alic, 1993). Whether bacteria are also able to degrade wood is still under discussion. Streptomycetes are able to perform some partial degradation. However, complete decomposition has yet to be shown with bacterial systems.

An interesting question in wood and lignin degradation is regarding the possible symbiosis of wood degrading fungi and bacterial populations at an oxic/anoxic border. Anaerobic bacteria able to convert lignin decomposition products and partially degrade these compounds have been described. The fermentation products of these organisms may serve as growth substrates for the lignin degrading fungi. Secondary metabolites of plants and microorganisms are often recalcitrant because they contain aromatic rings, heterocycles, and polyketides or are halogenated. Such compounds are not easily degraded, especially under anoxic conditions. If degradation does not lead to complete oxidation of carbon moieties to CO_2 , the formation of humic acids and fulvic acids and thus the production of humus ensues. This process is the driving force for soil genesis. Under aerobic conditions,

enzymatic reactions known from lignin oxidation are often involved (Bumpus and Aust, 1987; Hammel, 1989).

Degradation of aromatic and halogenated compounds

Under aerobic conditions, the chemically very stable aromatic ring can be broken by activities of mono- and di-oxygenases. While monooxygenases introduce one of the oxygen atoms of molecular oxygen into the organic molecule forming a hydroxyl group at one site of the ring, dioxygenases incorporate both oxygen atoms which leads to decyclization and ring opening. The linear compound can then be further oxidized after activation and fueled into general metabolic pathways. The aerobic degradation of aromatic compounds can be used to clean oil spills or other anthropogenic contaminations, especially applicable for the residual contamination after a first mechanical cleansing has been performed. Inoculation of a beach after an oil spill could show visible removal of the remaining oil within 1 year.

Under anoxic conditions, the ring opening seems more difficult and it had long been argued that this would not be possible. However, bacterial enrichment cultures could show that an anaerobic degradation of aromatic compounds is possible usually via activation and conversion to benzoyl CoA followed by ring reduction. These energetically unfavorable reactions are feasible with a thermodynamically favorable electron acceptor, e.g., when nitrate is available in an anaerobic respiratory chain. Thus, bacteria related to the nitrogen fixing genus *Azoarcus* link the degradation of aromatic compounds with denitrification. Many gene clusters with different substrate specificities have been identified to perform anaerobic degradation of different organic molecules including aromatic amino acids, benzene and its derivatives, phenols, and heterocyclic compounds. The linearized structures again can be fueled into metabolic pathways via acetyl CoA or propionyl CoA. Anthropogenic aromatic compounds can be degraded by these same processes, thus allowing complete decomposition and natural attenuation. The introduction of bacteria able to anaerobically degrade aromatic compounds into aquifers with (anthropogenic) contaminations opens the road to bioremediation of contaminated groundwater resources. In tertiary oil recovery, introduction of bacteria into the well to partially degrade the high molecular crude oil fraction uses bacterial enzymatic activities to form molecules of lower molecular weight from the tar fraction that then can be recovered.

Many anthropogenic contaminations contain halogen atoms which generally decrease metabolic degradation of the compounds. However, halogenated compounds are also known from natural sources. These include antibiotics with chloride or bromide atoms, plant-derived alkyl halides, or deterrents incorporated into, e.g., marine slugs or tropical frogs. Since nature already has learned to cope with these halogenated compounds, anthropogenic

halogenated substances can also be degraded by bacterial consortia, both aerobically and anaerobically (Abraham et al., 2002; Smidt and de Vos, 2004). Not only bacteria are known to be able to perform dehalogenation reactions, but also basidiomycete fungi can also degrade organohalogens (de Jong and Field, 1997). While aerobic dehalogenation is a simple enzymatic reaction, anaerobic dehalorespiration is an interesting field of research. In this case, the dehalogenation is coupled with electron transfer and directly coupled to ATP formation in an anaerobic respiratory process.

Use of microbes in bioremediation

The properties discussed above make the use of microbia or microbial consortia useful for bioremediation of different contamination scenarios. These include aerobic conditions such as in soil, anoxic condition such as in aquifers or sediments, and all imaginable sources of contamination from oil spill to xenobiotics such as plant protection chemicals or heavy metals. Some recent reviews are included to facilitate further reading on microbial degradation (Holtze et al., 2008; Johnsen and Karlson, 2007; Demnerova et al., 2005; Pieper, 2005; Kim and Rhee, 2003) and bioremediation (Watanabe et al., 2002; R  ling and van Versefeld, 2002; Schwitzguebel et al., 2002).

Summary

The biogeochemical cycles of the macronutrients carbon, nitrogen, sulfur, and phosphorus are dependent on microbial degradation of organic matter. Organic matter originating from carbon dioxide fixation, which is in terrestrial system usually performed by photosynthetically active bacteria and plant, is degraded to form carbon dioxide, either directly in one metabolic reaction or by cocultures in which the intermediate is released and taken up by another microbe. In addition, the formation of methane from CO₂ or acetate is possible. Thus, the carbon cycling involves CO₂, CH₄, and organic molecules. Nitrogen fixation of N₂ to NH₃ followed by fixation in organic amines constitutes one side of the cycle, while nitrification/denitrification releases the bound nitrogen into the atmosphere. The latter reaction sequences, i.e., oxidation of NH₃ to NO₂[−] or NO₃[−] and nitrate or nitrite respiration leading to N₂ formation, are dominant processes in the cycling of nitrogen. For the sulfur cycle, assimilation of sulfates and fixation into organic biomass, the oxidation of sulfur and reduction of sulfate or sulfite to elemental sulfur, or reduction of sulfur to H₂S are the main processes. Sulfur is a constituent of the amino acids cysteine and methionine and of Fe/S clusters in redox enzymes. Phosphate is generally not altered; however, there have recently been reports on the use of phosphite in an unusual energy fixation process.

These elemental cycles in the biogeosphere all involve steps of fixation within living biomass, and the degradation of dead biomass is an essential part in releasing the mineralized elements back into the cycle. Higher

organisms are not capable of using plant litter, e.g., directly and thus entirely dependent on microbial degradation processes to have sufficient minerals available for their nutrition. Properties of microbes for degradation can be useful in bioremediation approaches.

MICROBIAL ECOLOGY OF SUBMARINE CAVES

Francesco Canganella, Giovanna Bianconi
 University of Tuscia, Viterbo, Italy

Definition

Essential concepts, current investigations, and discussion.

In recent years, the search for the limit of biodiversity in extreme and/or uncommon environments led to the investigation of peculiar ecosystems such as deep-sea, subterranean niches, Antarctic cores, hydrothermal vents, and extraterrestrial sites.

Submarine caves and cavities have also been explored, some were mainly exploited as popular attractions for scuba divers, but some were shown to be of great interest for geologists, biologists, and microbiologists.

Available scientific data on these ecosystems are not abundant, particularly as far as biological disciplines are concerned. Most of the published works have been related to specific submarine cavities known as Blue Holes and Black Holes, as well as to submarine caves showing inner sulfidic emissions. A larger number of data are currently available regarding the microbiology of terrestrial caves, particularly on the microbial ecology of carbonate layers, sediments, bat guano, and flooding waters (Vlasceanu et al., 1997, 2000; Holmes et al., 2001; Engel et al., 2003; Northup et al., 2003; Sugita et al., 2005; Zhou et al., 2007), but these latter ecosystems are not part of the current review.

Blue holes and black holes

The so-called blue holes are underwater karst systems which can develop horizontally in a very extensive way and appear blue due to a combination of blue sky reflection with the white carbonate sand deposited in the cave (Smart et al., 1988; Mylroie et al., 1995; Schwabe et al., 1997; Marano-Briggs, 2000; Colantoni et al., 2003; Canganella et al., 2004). Most of these sites were found and described in Bahamas and Hawaii.

Other cavern systems are known as “black holes,” which are cave systems without known lateral passages and located in the interior regions of the larger Bahamian islands. Most black holes are located in the central to western side of the island of South Andros in the Bahamas (Figure 1), although one has been found on the northern transitional shore of the Grand Bahama Island. They are vertical cave systems which

Microbial Ecology of Submarine Caves, Figure 1 A schematic drawing of the South Andros black hole, (a) aerial view and (b) bathymetry. UWL, upper water layer; LWL, lower water layer; —, floor area not surveyed. (Reprinted from Schwabe and Herbert, 2004 *Black Holes of the Bahamas: what they are and why they are black*, *Quaternary International* 121: 3–11 with permission from Elsevier.)

develop from the surface downward and appear to have no direct link to the sea, except through rock fissures and local porosity (Schwabe, 1998; Schwabe and Herbert, 2004).

In both cave systems, as water exchange is severely restricted, physicochemical gradients are highly stable and even strict anaerobic conditions can develop with remarkable hydrogen sulfide concentrations (from 5 μM to 6 mM).

Submarine caves with sulfidic water springs

A unique marine ecosystem is represented by the submarine caves of Capo Palinuro (Salerno, Italy), of which 13 have inside sulfidic springs exhibiting temperatures up to 25°C that remarkably affect the surrounding ecosystem.

Preliminary investigations concerning the submarine speleology of the site have been carried out since the mid 1980s, but only after 1990 an extensive biological knowledge was achieved. Several ecological and geological studies were performed (Alvisi et al., 1994a, b; Mattison et al., 1998), particularly on the “Grotta Azzurra” (Figure 2). The cave may be separated into two topographically distinct regions: a weakly illuminated outer region and an inmost dark region (Snow Hall). The latter is

characterized by the presence of sulfur springs that arise from fissures in the cave floor. Currently, no other submarine caves with sulfide springs have been reported.

Microbiological studies

The blue holes

Abundant microbial development has been observed in these cave systems, usually linked to temperature anomalies in the range of 36–41°C as recorded by investigators. Marano-Briggs (2000) reported temperatures up to 41°C in the Tarpon Blue Hole, supporting the theory that the mass population of anoxygenic phototrophic bacteria present at a specific water layer may dissipate excess light energy by heat. A dense layer of purple sulfur bacteria

Microbial Ecology of Submarine Caves, Figure 2 A drawing map of the “Grotta Azzurra” showing both entrances, halls, and freshwater circulation.

was indeed found at 4.5–5.5 m depth in the estuarine Tarpon Blue Hole and the dominant population was represented by *Chromatiaceae* species. These bacteria are capable either of photolithoautotrophic growth with sulfide or elemental sulfur under anoxic conditions in the light or of chemo-organotrophic growth under micro-oxygenic conditions in the dark. Their abundance in the site was consistent with their physiological traits, and among them a phototrophic bacterium in particular was identified as a novel strain of *Marichromatium purpuratum* that contained okenone instead of spirilloxanthin as its major carotenoid.

Recently, microbiological studies on a blue hole discovered in the Indian Ocean (Canganella et al., 2004) were preliminarily performed in order to investigate the distribution of microbial populations along the water column and in the bottom sediment of the cave. In Figure 3, the DGGE analysis carried out shows how bacterial populations are distributed among surface layers, mid- and deep-layers, indicating in particular a similar biodiversity between 30 and 50 m depth. The same was investigated by the Biolog system, particularly for anaerobic populations.

The molecular investigation showed that at surface there was a complex microbial community showing several peculiarities with respect to standard pelagic seawater. Characteristic species were *Thioalkalivibrio* and *Thioploca* within the Gamma-Proteobacteria and *Desulfosarcina* and other Delta-Proteobacteria; sequences within the Delta-Proteobacteria related to sponge symbionts were also found. Subsurface bacteria present in the water column appeared dominated by Alpha-Proteobacteria represented by sequences related to photoorganotrophs (*Rhodovibrio*-related), methanotrophs, and coral surface-related bacteria.

Near the bottom, although the Alpha-Proteobacteria were still well represented, the proportion of Delta-Proteobacteria increased. These Delta-Proteobacteria represent sulfate-reducing bacteria mainly belonging to the Desulfobacteriaceae, or related to *Desulfonanticus*, *Syntrophus*, and others related to marine and salt-marsh uncultured bacteria.

The black holes of the Bahamas

The water in these holes appears black in color due to the presence of a 1 m thick white microbial veil located within the upper third of the water column (18–19 m), at the boundary between the oxygenic low salinity upper water mass and the denser anoxic saline water layer. The boundary between the two water masses is characterized by sharp discontinuities in physicochemical gradients: salinity increased from 12 to 35 psu and temperature from 29°C to 36°C; pH decreased from 8.6 to 6.45 as well as dissolved O₂ from 6 mg/l to <1 mg/l. Morphological microscopic observations of collected samples showed mainly nonmotile spherical and motile rod-shaped purple sulfur bacteria. The dominant members of this warm (36°C), saline, and sulfide-rich layer have been identified

Microbial Ecology of Submarine Caves, Figure 3 DGGE analysis of the water column and bottom sediment of the blue hole in the Indian Ocean.

as anoxygenic phototrophic bacteria belonging to the genera *Allochromatium* and *Thiocapsa* and showed population densities $>10^7$ viable cells/ml. These bacteria grow well in the presence of sulfide and carbon dioxide in the light. During photoautotrophic growth sulfur globules are stored intracellularly as intermediate oxidation products. Moreover, the intracellular photosynthetic membranes are of the vesicular type, and bacteriochlorophyll *a* and carotenoids of the normal spirilloxanthin series are present (Herbert et al., 2005). Calculations made by these authors revealed that the layer of anoxygenic phototrophic bacteria in the South Andros black hole may have a biomass content of approximately 5.06 ton dry weight.

Microbial Ecology of Submarine Caves, Figure 4 A phylogenetic tree based on 16S rRNA gene sequence comparison, including representative heterotrophic isolates from the "Grotta Azzurra."

The marine caves of Capo Palinuro

The emergence of sulfidic water in some of the caves (particularly in the "Grotta Azzurra," "Grotta Sulphurea," and "Grotta di Cala Fetente") gives rise to an unusual situation, characterized by abiotic as well as biotic fluctuations, represented by emissions from sulfidic springs and higher concentration of sulfur-utilizing bacteria following each outflowing event, respectively. Warm sulfidic water of reduced salinity enters the Snow Hall (Grotta Azzurra),

from fissures in the bottom rocks, and rises above the more dense seawater to form a thermocline and chemocline as a visible boundary at a depth of about 9.5 m. The geochemistry of water samples from the Grotta Azzurra was extensively reported by Mattison et al. (1998): above and below the chemocline temperatures were 24.0 ± 0.2 and 22.8 ± 0.3 , respectively; NaCl concentrations (%) were 2.6 ± 0.1 and 3.0 ± 0.1 , respectively; pH values were 7.22 ± 0.02 and 8.15 ± 0.25 , respectively.

Microbial Ecology of Submarine Caves, Figure 5 (a) A SEM picture of a sample collected in the bacterial mat on the vault of the “Grotta Azzurra”; (b) a SEM picture of a sample collected in the bacterial mat on the vault of the “Grotta Azzurra”; (c) A SEM picture of a sediment sample collected nearby a sulfataric spring along the main entrance of the “Grotta Azzurra.”

The present ecosystem is biologically unique particularly because of the following points: (1) the peculiar emissions represent the only available model in shallow waters resembling the deep-sea hydrothermal vents (Canganella, 2001); (2) alike what happens in usual submarine caves, the development of micro- and macro-fauna increases with the decrease of irradiation; (3) the freshwater flow is placed above the seawater and, inside the cave, an interface between the warm/anaerobic upper zone (H_2S -enriched) and the cold, sulfurless lower zone can be observed; (4) giant forms, particularly among *Cnidaria* and *Porifera*, occur mainly along the aerobic/anaerobic interface (Alvisi et al., 1994a, b).

During the last decade both, “Grotta Azzurra” and “Grotta Sulfurea” have been investigated. Some preliminary data on the lithotrophic microflora were published (Mattison et al., 1998), and other studies were performed in order to (1) investigate the microscopic structure of bacterial mat and (2) to understand both the taxonomy and physiology of heterotrophic bacteria inside the “Grotta Azzurra” (Canganella and Bianconi, 1999, 2003). The 16S rRNA genes analysis (Figure 4) showed that heterotrophic isolates were closely related to the genera *Escherichia*, *Citrobacter*, *Vibrio*, and *Bacillus*.

In addition to the analysis of the heterotrophic microflora, recently a preliminary molecular investigation was performed to evaluate the biodiversity of both eubacterial and archaeal populations (Canganella F. and Bianconi G. 2009).

Some bacterial sequences were closely related to the sulfur-oxidizing bacterial group, involving the genus *Beggiatoa* and *Thiothrix*. Showing that these microorganisms may well represent a major microbial community in the bacterial mat of the cave. Other bacterial sequences were phylogenetically linked to the Delta-proteobacterial group, particularly to sulfate-reducing bacteria. Archaeal sequences were partially related to methanogen archaeal group, but the phylogenetic distance was still remarkable; so the involvement of a novel archaeal group can be considered. Other archaeal sequences were related to MG-1,

which is a common uncultivable archaeal group in marine environment.

As regards the microscopic structure of bacterial mat inside the cave and sediments collected nearby a sulfidic spring along the main entrance of the “Grotta Azzurra,” the distribution of various morphological forms is shown in Figures 5a–c. Filamentous microbial forms were abundant and morphologically similar to *Beggiatoa*, *Desulfonema*, *Leucothrix*, or *Thiothrix* species; morphology was, however, not enough to identify such organisms. Several cells showing either coccoid or rod morphologies were also observed in samples collected inside as well as outside the mat.

Conclusions

As regards the blue and black holes, it has been shown that the dominant anoxygenic phototrophic bacteria in the microbial layers are member of the *Chromatiaceae* (Imhoff et al., 1998). The presence of dense phototrophic populations of purple sulfur bacteria particularly explains why the South Andros black hole appears black and not blue. Moreover, the sulfide profile data obtained in this site showed that sulfide concentration was low (30 μM) suggesting that biomass production by the purple sulfur bacteria was sulfide rather than light limited.

Another important point to consider is that the dense microbial phototrophic population probably plays a significant role in enhancing carbonate CO_2 -mediated dissolution operated by heterotrophic bacteria. The effects of microbiological activity on degradation of limestone deposits have been described by several authors (Ehrlich, 1996; Golubic and Schneider, 1979; Paine et al., 1993) and similar observations were reported for the Bahamas cave systems from Smart et al. (1988).

Recent studies have shown that biotic oxidation of sulfide into sulfuric acid can occur in anoxic marine ecosystems due to chemoautotrophic sulfur-oxidizing bacteria such as *Beggiatoa* (Mattison et al., 1998; Vlasceanu et al., 1997, 2000). This biological process may also be involved in carbonate dissolution for the South Andros black hole but the role of sulfur-oxidizing bacteria needs

to be evaluated by further investigations. The same consideration may be valid for the blue hole in the Indian Ocean. In this site the occurrence of highly toxic sulfide and low oxygen content caused the death of the macrobenthos in deep waters, where a chemolithoautotrophic microbial community settled on the cave walls as mucilaginous and hardened short filaments of bacterial origin whose study is still in progress.

In the "Grotta Azzurra" cave of Capo Palinuro, fluids emitted from active springs with maximum temperatures of 25°C and enriched in dissolved sulfur species (H_2S , $\text{S}_2\text{O}_3^{2-}$) allowed the development of a significant micro- and macro-fauna, resembling in some way what occurs around hydrothermal vent sites (Jeanthon, 2000; Canganella, 2001).

Morphological/physiological observations were previously carried out by Mattison et al. (1998) on microbial mats in the "Grotta Azzurra" of Capo Palinuro. In recent studies both sampling and isolation were carried out regardless of the chemocline. Future investigations on the distribution of microbial populations will eventually lead to discrimination between more thermotolerant and more mesophilic species living above or below the chemocline; the same can be true for noncultivable species.

The characterized heterotrophic isolates partially represent the microbial ecology of the site, showing its biological complexity at a phylogenetic level. Moreover, the wide resistance of isolates to temperature, salinity and pH may be associated with the specific ecological system, an hypothesis that certainly deserves further investigations.

In general terms, similar environmental traits can be described for the blue hole in the Indian Ocean and the submarine caves of Palinuro Cape; first of all, the presence of elevated concentrations of hydrogen sulfide, ranging from 5 μM to 200 mM. A chemocline in the water column may be clearly observed in the blue hole of the Indian Ocean or in the black hole of the Bahamas, whereas in the submarine caves of Palinuro Cape the environmental borderline inside the habitat is represented by the threshold between upper anoxic, sulfide-rich freshwater and lower seawater.

As regards the autoctonous microflora, the blue hole of the Indian Ocean showed the presence of filamentous forms as described in the Palinuro caves but mucilaginous forms on the rocky side walls were not found in the latter; moreover sulfate-reducers and sulfide-oxidizers were also detected in both systems.

Some microbiological features of both systems are also shared with other sulfide-rich environments, such as the presence of anaerobic methane oxidizers, filamentous bacteria, anaerobic phototrophs, and archaeal strains. However, the incomplete data set on the inhabitant microflora, the geological diversity of the systems described earlier, and their different geographical locations make a microbiological comparative study difficult. With no

doubts the combination of different approaches and techniques may be a powerful tool to investigate further such astonishing ecosystems by a multiphasic approach.

As a matter of fact, further investigations on the microbial diversity in sulfide-rich, either marine or freshwater, caves will be based on traditional techniques of isolation coupled to simultaneous molecular investigations.

Definition

Microbial mats are often centimeter-thick multilayered structures of microorganisms, mainly bacteria, archaea, fungi, and sometimes these mats are enriched with protozoans. Microbial biofilms are in contrast much thinner (10–100 µm) than microbial mats and have a different architecture (Characklis and Wilderer, 1989). Microbial mats grow at interfaces between different types of material, mostly on moist surfaces, but some of them are also found in dry environments like deserts (e.g., Stal and Caumette, 1994; Characklis and Wilderer, 1989). They colonize environments located in high altitude, they are common in the Deep Biosphere, in subterranean environments with temperatures from –40°C to +120°C. There are also common as endosymbiotic structures, for example, in animals. They are very common in extreme environments like hydrothermal vents, cold seeps, and alkaline and hypersaline lakes (Van Dover, 2000; Pederesen, 2006; Arp et al., 2003; Riding and Awramik, 2000).

Geobiological implications

A microbial mat consists of several layers dominated by specific types of microorganism (Figures 1 and 2). Although the composition of individual mats varies depending on the environment, as a rule the by-products of each group of microorganisms serve as energy source for other groups. Different types of microorganisms dominate different layers based on their comparative advantage (Canfield and Des Marais, 1993; Allison et al., 2000). Ecological relationships between different groups are a combination of competition and cooperation. The metabolic capabilities of bacteria and archaea are generally depend on their phylogeny. In a wet environment where sunlight is available, the upper layers are generally dominated by aerobic consortia like cyanobacteria (Figure 1), while the lowest layers are normally dominated by anaerobic microorganisms such as sulfate-reducing bacteria, methanogenic and/or methanotrophic archaea, or general archaea. Marine mats may grow to a few centimeters in thickness, of which only the top few millimeters are oxygenated. Microbial mats are held together and bound to their substrates by sugar- and protein-rich extracellular polymeric substances (EPS), which they secrete (Decho et al., 2005; Wingender et al., 1999). In many cases, some of these microorganisms form filaments (threads), which tangle and thus increase the microbial

Microbial Mats, Figure 1 Phototrophic 5-cm-thick microbial mat from a hypersaline lake (Lake 21) on Kiritimati Island (Kiribati, Line Islands). 1 – Orange layer with cyanobacteria; 2 – Green layer with green bacteria, zone with the highest diversity of prokaryotes; 3 – Purple layer, zone with photosynthetic non-sulfur purple bacteria (alpha-, and beta proteobacteria); 4 – Gray layer with sulfate-reducing bacteria and archaea, zone of heavy carbonate and gypsum mineralization within degrading extracellular polymeric substances (EPS). The entire mat is interspersed with authigenic, spherulitic aragonite, and gypsum crystals that are growing within EPS.

colonies structural strength, especially if the filaments have sheaths.

Microbial mats are the earliest complex form of life on Earth. There is a fossil record from 3,500 million years ago, and they have always been the most important members and maintainers of earth ecosystems (Allwood et al., 2006; van Kranendonk, 2007). Early Precambrian microbial mats are the first evolved highly complexly organized multicellular organisms. Microbial mats occasionally mineralize if the ionic strength in the aquatic environment allows it. The mineralized structures are known as stromatolites and thrombolites and they represent the most important organo-sedimentary fabrics since the early beginning of microbial life on earth (Burne and Moore, 1987; Riding, 2000). Originally, microbial mats first occurred at hydrothermal vents for energy. Since the late Precambrian microbial mats have also played an important role at cold hydrocarbon seeps, so-called Cold Seeps. Most of the Cold Seeps are methane vents coupled with hydrogen sulfur microbial metabolism (Reitner et al., 2005) (Figure 2). However, phototrophic microorganisms such as cyanobacteria, unicellular algae (e.g., diatoms), and related consortia are the most abundant microorganisms in the formation of microbial mats (e.g., Arp et al., 2010). Within subterranean environments iron-oxidizing microbial consortia show a strong ability to form thick microbial mats (Kurz et al., 2010).

Microbial mats are the context within which the first multicellular organisms evolved. Sponges are, for

Microbial Mats, Figure 2 Anaerobic microbial mat from a cold seep environment of the Black Sea. Black mat represents the outer margin of the microbial mat. This mat is dominated by ANME 2 archaea and greigite-bearing sulfate reducing bacteria (GHOSTDABS field, for details see Reitner et al., 2005; Reitner, 2010). Orange-pink mat represents an archaea-(ANME1)-dominated mat portion. The green mat represents the inner most area close to the methane vent. This mat is also dominated by ANME archaea, Crenarcheota, and anaerobic bacteria. The entire mat is stabilized by authigenic methane-related aragonite and calcite crystal aggregates, which are also growing within EPS.

example, highly evolved microbial mats with a mutual relationship with eukaryote choanoflagellates. May be the Vendobionta, large Ediacaran organisms with characteristic quilt bauplan are part of well-developed microbial mats and may themselves be large colonies of various microbial communities (Seilacher, 1999; Schieber et al., 2007; Steiner and Reitner, 2001).

Conclusion

Microbial mats are normally cm-thick microbial communities often related with microbially induced mineral precipitates (calcite, aragonite, iron-oxides etc.). Characteristic for these mats is a multilayered structure which represents various microbial communities with different metabolic activities. In phototrophic microbial mats (e.g., cyanobacteria) dominate the uppermost layers whereas within the deep layers of the mats anaerobic microbes dominate like sulphate reducing bacteria and archaea. Microbial mats are complex multicellular systems which exhibit some accordance to basic metazoans like sponges. It is speculated that microbial mats are a model for the basic metazoan bauplan.

MICROBIAL SILICIFICATION – BACTERIA (OR PASSIVE)

Kurt O. Konhauser, Brian Jones
 University of Alberta, Edmonton, Alberta, Canada

Definition

The encrustation, impregnation, and/or replacement of microbial tissue by silica minerals, usually opal-A.

Overview

Silica precipitation is an important geological process in many modern geothermal systems where venting of super-saturated solutions leads to the formation of finely laminated siliceous sinters around geyser and hot spring vents and on their discharge aprons. The spring waters, which typically originate from deep, hot reservoirs, at equilibrium with quartz, commonly contain dissolved silica concentrations significantly higher than the solubility of amorphous silica at 100°C (Fournier, 1985). Therefore, when these fluids are discharged at the surface, decompressional degassing, rapid cooling to ambient temperatures, evaporation, mixing, and changes in solution pH collectively cause the solution to suddenly become supersaturated with respect to amorphous silica (also known as opal-A). In such supersaturated solutions, the discharged monomeric silica, Si(OH)₄, polymerizes, initially to oligomers (e.g., dimers, trimers, and tetramers), and eventually to polymeric species with spherical diameters of 1–5 nm, as the silanol groups (–Si–OH–) of each oligomer condense and dehydrate to produce the siloxane (–Si–O–Si–) cores of larger polymers. The polymers grow in size through Ostwald ripening such that a bimodal

composition of monomers and particles of colloidal dimensions (>5 nm) are generated. The latter stay in suspension due to the external silanol groups exhibiting a residual negative surface charge, they coagulate via cation bridging and nucleate homogeneously, or they precipitate heterogeneously on a solid substratum (Ihler, 1979).

Siliceous sinters commonly contain numerous mineralized microorganisms (e.g., bacteria, algae, fungi) in varying stages of preservation (Jones et al., 1997; Konhauser et al., 2001). Examination under the scanning or transmission electron microscopes (SEM/TEM) shows that their preservation typically involved the precipitation of spheroidal, amorphous silica grains on (i.e., encrustation) or within (i.e., impregnation, replacement) the walls and/or sheaths of the microbes. The manner in which a particular microbe is preserved depends upon the balance between the timing of opal-A precipitation/impregnation and decay of the soft tissues of the microbe (Figure 1). In many cases, a microbe merely acts as a template as opal-A is precipitated around its outer surface. Such encrustation begins with the attachment of preformed silica colloids, on the order of only 10 s of nanometers in diameter, to the cell surfaces (Figure 2a). Those silica particles then grow in size, and may reach micrometer diameters in size. If opal-A precipitation is sustained, those particles invariably coalesce until the individual precipitates are no longer distinguishable, resulting at times in entire colonies being cemented together in a siliceous matrix (Figures 2b and 3a–d).

Replacement, which involves impregnation of the organic tissue by opal-A, can lead to superb preservation of the microbes (Figure 3e). Jones et al. (2001, their Fig. 8), for instance, illustrated silicified specimens of

Calothrix in which the sheath and outer splayed lamina are still evident. Septa may also be preserved in this way (Figure 3h). If encrustation is the sole process, then many silicified filamentous microbes will be evident only as hollow tubes (Figure 3g and i). Subsequent filling of that tube with opal-A will produce a solid opal-A rod, with the size of the original lumen/filamentous microbe only being apparent if there is a discontinuity preserved (e.g., Figure 3f). Irrespective of the nuances, the silicification of microbes must take place quickly if they are to be preserved, and certainly before the microbes undergo any degree of desiccation and degradation (Jones et al., 2001). This notion is supported by the fact that the three-dimensional form of most microbes is still apparent following silicification (Figure 3j–l). Indeed, some microbes are coated with silica while they are still viable (Phoenix et al., 2000) and it seems that silicification must take place in a matter of days in order for the three-dimensional morphology to be preserved.

Plant material bathed in the polymerizing solutions may be encrusted, impregnated, and/or replaced with opal-A similar to microbes. In many of the hot spring systems of New Zealand, for example, grass stems, pieces of wood, and leaves are heavily encrusted with opal-A but their tissues have usually not been replaced. In fact, the grass is commonly still growing even though encased by opal-A. In contrast, wood and leaves on the discharge apron around Geysir, Iceland that have been superbly preserved through replacement have not been encrusted with opal-A. Similar comparisons apply to some of the microbes. The factors that dictate encrustation as opposed to replacement are currently not understood as there are no obvious correlations between preservation style and the chemical attributes of the associated waters.

Microbial Silicification – Bacteria (or Passive), Figure 1 Schematic longitudinal cross-section of a sheathed filamentous microbe showing morphological variations that can develop as a result of silicification. Modified form Jones et al. (2001, their Fig. 10).

Microbial Silicification – Bacteria (or Passive),

Figure 2 Transmission electron micrographs (TEM) of cyanobacteria from a geyser outflow channel at Strokkur, Iceland. (a) Cell showing abundant silica spheres on, and within the surrounding sheath material. (b) Colony of unidentified cyanobacteria that are completely encrusted by silica matrix. Remnants of cytoplasm are still evident inside some cells. Scale bars = 3 μm .

Despite the fact that many silicified microbes appear to be superbly preserved, only a limited number of features are usually apparent. Even in the best-preserved specimens, features are generally limited to overall morphology, filament diameter, presence/absence of branching, presence/absence of a sheath, and/or size of cells. Identification in terms of extant taxa is usually difficult because the limited numbers of morphological features apparent in the silicified forms are insufficient unless they are particularly distinctive in some way. This issue is compounded by the fact that many extant taxa are defined by their DNA characteristics and/or the conditions under which they were cultured in a laboratory setting. In most cases,

therefore, the identification of silicified microbes must be done with caution.

The role that the microbes (and some plant material) play in their own silicification has been a matter of debate. Being soft-bodied organisms they do not “actively” mediate amorphous silica formation in the manner of diatoms, radiolarians, and sponges. In contrast, bacteria, algae, and fungi facilitate silica precipitation by creating a suitable microenvironment and/or template for opal-A precipitation. For example, they may produce organic ligands that promote the mineralization process (Lalonde et al., 2005), or they may change the pH immediately around the cell through their metabolic activity, and in this regard, induce supersaturation with respect to opal-A (Amores and Warren, 2007). At other times, the microbes may simply act as solid surfaces for silica precipitation and exert no direct influence over the process (Walter et al., 1972).

Experimental evidence seems to indicate that the microbial role in the silicification processes is incidental and not limited to any particular taxa. First, microbes have little affinity for monomeric silica, even at high bacterial densities and low pH conditions where most organic functional groups are fully protonated and neutrally charged (Fein et al., 2002). Second, at supersaturated conditions, there appears to be very little difference in the rates or magnitude of silica precipitated between microbial and microbial-free systems (Yee et al., 2003; Benning et al., 2004). Third, silicification occurs on dead cells, and continues autocatalytically and abiogenically for some time after their death due to the high reactivity of the newly formed silica. This notion is supported by microscopic examination of thermal spring deposits where it has been shown that the silica precipitated in the porous spaces between filaments has the same basic motif as the silica precipitated on the original filaments (Jones et al., 1998). From these observations, it can be inferred that at high silica levels there is such a strong chemical driving force for silica polymerization, homogeneous nucleation, and ultimately silica precipitation that there is no obvious need for microbial catalysis.

Despite the observations above, the fact that there are species-specific patterns of silicification infers that some microbes may influence silicification in some way. The initial coating of opal-A spheres around microbes in Iodine Pool in the Waimangu geothermal area, for example, are consistent in size and highly organized in terms of their distribution (Jones et al., 2004, their Fig. 9). In contrast, the outer layer of opal-A beads is larger, variable in diameter, and follows no set distribution pattern. Thus, it seems that some aspect of the microbes may have influenced the initial phase of opal-A precipitation but not later phases. This seems feasible given that the initial layer of opal-A precipitates would have effectively encased the microbes and thereby isolated their surfaces from the water. Furthermore, different microbes exhibit different degrees of silicification. This is not surprising

Microbial Silicification – Bacteria (or Passive), Figure 3 (Continued)

given that the actual mechanisms of silicification rely, in part, on the microbes providing reactive surface ligands that adsorb silica from solution, and accordingly, reduce the activation energy barriers to heterogeneous nucleation (Konhauser et al., 2004). This means that cell surface charge may have a fundamental control on the initial silica sorption process.

At present there appears to be three different mechanisms by which microbes bind dissolved/colloidal silica; (1) hydrogen bonding, (2) cation bridging, and (3) electrostatic interactions (Figure 4). In the first instance, Phoenix et al. (2002) showed that the polysaccharide-rich sheath of *Calothrix* is electrically neutral at pH 7, and opal-A precipitation occurs through hydrogen bonding between the hydroxy groups associated with the sugars and the hydroxyl ions of the dissolved silica. Second, the highly anionic nature of most bacteria, such as *Bacillus subtilis*, limits opal-A from occurring on the cell wall, likely as a result of electrostatic charge repulsion between the anionic ligands of the organic functional groups and the negatively-charged silica species (Phoenix et al., 2003). Therefore, in order for silica to sorb, some form of cation bridge (e.g., Fe^{3+} , Al^{3+}) is necessitated (Fein et al., 2002). Third, some species, such as *Aquificales*, produce protein-rich biofilms that contain sufficient cationic amino groups (NH_4^+) to electrostatically react with dissolved silica (Lalonde et al., 2005).

Given that a wide assortment of microbes live in environments where opal-A is being precipitated, it is important to determine if those species survive the mineralization process. In this regard, Phoenix et al. (2000) tested cell viability during biomineralization, and observed that experimental encrustation of *Calothrix* by silica was not notably detrimental to the organisms. Even after 12 days of incubation in a 600 mg l^{-1} silica solution, during which many of the filaments developed extensive mineral crusts up to $5 \text{ }\mu\text{m}$ thick, the cells still fluoresced,

they continued to generate oxygen and the mineralized colonies exhibited comparable rates of photosynthesis to the non-mineralized colonies. Interestingly, silica precipitation only occurred upon the outer surface of sheath material from viable cyanobacterial cells – no viable cells exhibited internal or cell wall mineralization. This contrasts with dead and lysed cells where mineralization of the cell wall and cytoplasm had occurred. In a more recent study with the thermophilic chemolithoautotroph *Sulfurihydrogenibium azorense*, Lalonde et al. (2005) showed that the bacterium, when grown as a H_2 -oxidizer, reacted to increasing silica concentrations by producing excess protein that appears linked to biofilm production. Since silicification was not observed directly on the cell surface, they proposed that *S. azorense* may prevent cellular silicification to some degree by providing abundant reactive sites in the biofilm matrix and regulating biofilm production appropriately, with potential contributions from metabolic effects. Thus, it appears that some microbes can thrive in silica-rich environments because they form protective layers that isolate the cells from the potentially damaging effects of silicification.

Summary

Microbial silicification includes the encrustation, impregnation, and replacement of cells by amorphous silica. Most microbes play a passive role in the mineralization process by providing organic surfaces that facilitate the binding of silica polymers and colloids from solution. These sorption reactions can occur by either (1) hydrogen bonding between dissolved silica and cell hydroxy functional groups, (2) cation bridging between anionic cell functional groups and the silica, or (3) direct electrostatic interaction of silica with cell surface ammonium groups.

MICROBIAL SURFACE REACTIVITY

David A. Fowle, Kurt O. Konhauser
 University of Alberta, Edmonton, Alberta, Canada

Definition

The chemical charge on a cell surface caused by the deprotonation/protonation of organic functional groups.

Overview

Similar to an aqueous organic acid, bacterial cell surfaces can either bind or release protons (H^+) into solution depending upon the solution pH. In the case of the latter, this deprotonation process, which accurately mimics a number of the functional groups associated with cell surfaces, leads to the formation of an organic anion, or ligand. Unlike an aqueous organic acid, which exhibits proton buffering over a narrow pH range (± 1 –2 units), bacterial cell walls have continuous buffering capacity over a wide range of pH values which span most geologic settings (pH 2–10). Ultimately, most surface reactivity of bacteria with its external environment results from the enhanced electronegativity of the cell wall as these functional groups deprotonate. In its most simplistic form, deprotonation can be expressed by the following equilibrium reaction:

where B denotes a bacterium to which each protonated ligand type, A, is attached. The distribution of protonated and deprotonated sites can be quantified with the corresponding mass action equation:

$$K_a = \frac{[B - A^{-1}][H^+]}{[B - AH^0]}, \quad (2)$$

where K_a is the dissociation constant; $[B - A^{-1}]$ and $[B - AH^0]$ represent the concentration of exposed deprotonated and protonated ligands on the bacterium, respectively (in mol l^{-1}); and $[H^+]$ represents the activity of protons in solution. Each functional group has its own K_a , and based on equation (2), the pH at which $[B - A^{-1}]$ and $[B - AH]$ are equivalent is known as the pK_a value, where $pK_a = -\log_{10} K_a$. At $pH < pK_a$ surfaces are protonated and at $pH > pK_a$ they are deprotonated.

The ionization of functional groups provides an electrical charge ($[L]_T$ represented in mol mg^{-1}), which in the laboratory can be calculated as a function of pH from the difference between total base or acid added to a suspension of organic material and the equilibrium H^+ and OH^- ion activities (Reaction 3):

$$[L]_T = \frac{C_a - C_b \pm [OH^-] - [H^+]}{S} \quad (3)$$

Microbial Surface Reactivity, Figure 1 Experimental data demonstrating the buffering capacity of *Bacillus subtilis* during acid–base titration (circles; molality of protons added normalized with respect to the wet weight of bacteria present) and zeta potential (diamonds) gathered from titrations of *Bacillus subtilis* in 0.01 M NaNO_3 that were cultured in tryptocase soy broth.

The components, C_a and C_b , are the concentrations of acid and base added, respectively; n_{OH^-} and n_{H^+} are the number of moles of OH^- and H^+ in the solution at the measured pH, respectively; while “S” is the quantity of the solid (usually expressed in dry weight, i.e., mg). When such calculations are done over an entire pH range, an acid–base titration curve is created that shows the pH range over which some functional groups are chemically active and how the net surface charge of the organic surface varies with pH (Figure 1). A large difference in the total base or acid added and the free H^+ ion activity indicates significant pH buffering and a high concentration of surface functional groups. On the titration curve this is shown by a steep slope. A small difference in the total base or acid added and the free H^+ ion activity indicates weak pH buffering and a low concentration of surface functional groups. This translates into a gentle slope on a titration curve. In terms of microbial biomass, carboxyl groups account for the buffering capacity from pH 2–6 (Reaction 4), phosphate groups from pH 5–8 (Reaction 5), amino groups at pH > 8 (Reaction 6), and hydroxy groups deprotonate at pH values above 10 (Reaction 7) (see Konhauser, 2007).

As a consequence of the deprotonation reactions, the microbial surface develops an electrical charge. Therefore, when subjected to an electric field, microorganisms move in the direction, and at a rate, commensurate with the polarity and density of the overall surface charge. This process is termed electrophoresis, and the electrophoretic mobility of a microbial suspension can be quantified by measuring their velocity in an electric field. This measurement can, in turn, be used to calculate the zeta potential (ζ), using the Smoluchowski equation below (Hunter, 2001):

$$\zeta = \frac{\eta\mu}{\epsilon_0\epsilon} \quad (8)$$

The component “ μ ” is the electrophoretic mobility of a particle; ϵ_0 and ϵ are the relative dielectric constants of the vacuum and solution, respectively; and η is the viscosity of the solution. The zeta potential reflects the electrical potential at the interfacial region (viewed as a shear plane) separating an inner layer, where cations are held tightly in place and move with the bacterium, and an outer layer where ions are mobile (Wilson et al., 2001). The greater the absolute value of the ζ potential, the greater the charge

density on the surface (Blake et al., 1994). The electrophoretic mobility (and zeta potential) is pH dependent because the activity of protons in solution controls the ionization reactions of functional groups at the microbial surface (Ahimou et al., 2001) (Figure 1). This leads us to the concept of isoelectric point, which is defined as the pH value where the net surface charge of a solid is zero. The isoelectric point can be estimated from acid–base titrations, but it can also be directly measured with electrophoretic mobility experiments because at the isoelectric point microbes do not exhibit motion in an electric field. The isoelectric point of bacterial cell walls is typically between pH 2–4 (Harden and Harris, 1953). This means that at low pH, when the surface functional groups are fully protonated, bacteria are either neutral or positively-charged, the latter being the result of a cell possessing abundant amino groups. Meanwhile, at the growth pH of most bacteria, cells inherently display a net negative charge and the magnitude of negativity increases with higher pH values. As a result, under low pH conditions, most bacterial surfaces behave hydrophobically, but with an increasingly hydrophilic nature with increasing pH.

One of the major challenges faced by the researchers today is how to translate acid–base titration data in terms of cell wall biochemistry. Ascribing pK_a values from a titration curve to specific functional groups can be problematic because there is often significant variation in pK_a values for the same functional group. This occurs because the magnitude of the dissociation constant is controlled by the structure of the molecule to which it is attached (see Martell and Smith, 1977 for details). Consequently, a single carboxyl group in two different organic acids will have different pK_a values, as will an organic acid with multiple carboxylic groups. As might then be expected, the pK_a for a carboxyl group on one microbial species versus another could yield widely different values simply because of subtle conformational variations within the wall macromolecules. Furthermore, titration experiments are only able to resolve those groups that contribute significant amounts of protons to solution. Minor groups are simply undetectable with the resolution of current techniques. It is thus important to keep in mind that the model-derived binding sites do not directly represent the functional groups of the cell surface; their identity can only be inferred by comparison of the functional group pK_a values with pK_a values of model compounds. Unequivocal identification of the types of functional groups responsible for acid–base buffering may be obtained by spectroscopic techniques, such as Fourier transform infrared spectroscopy (FTIR), calorimetry or gas/liquid chromatography of cell wall extracts. For instance, Yee et al. (2004) and Jiang et al. (2004) used infrared spectroscopy to examine the pH dependence of deprotonation of bacterial cell-wall functional groups. Although not all pH conditions were studied, it was clear that the vibrational frequencies of carboxyl type groups increased with increasing pH. Calorimetric measurements of protonation reactions on bacterial surfaces indicate

these reactions are exothermic with relatively small site-specific entropies (Gorman-Lewis et al., 2006). This provides more evidence that (1) hydrogen bonding between protonated and deprotonated sites likely stabilizes the cell wall, and (2) bacterial cell wall functionalities are similar to multifunctional organic acids rather than simple organic acids.

Summary

Microbial surface reactivity results from the protonation and deprotonation of the organic moieties of microbial cell surfaces including carboxyl, phosphate, amino, and potentially hydroxyl groups. These groups behave similarly to multifunctional organic acids – they hydrogen bond with each other which leads to negative charge on the cell wall as pH increases. At most environmentally relevant pH values, microbial cell surfaces will possess a net negative charge, and therefore, will interact with positively charged cations or mineral surfaces.

²University of Miami, Miami, FL, USA

Synonyms

“Cryptalgal sedimentary rock” (Aitken, 1967); Microbolite (Riding, 1991)

Definition

Microbialite: “Organosedimentary deposits that have accreted as a result of a benthic microbial community trapping and binding sediment and/or forming the locus of mineral precipitation” (Burne and Moore, 1987), or “Benthic microbial deposits” (Riding, 1991).

Introduction

In this encyclopedia, microbialite is discussed under two chapters: (1) modern and (2) fossil. This part discusses modern microbialites, with emphasis on processes of formation. The fossil extension and classification of microbial deposits (fossil forms being more diverse) are treated in the “fossil microbialite” section of the encyclopedia (see Chapter *Microbialites, Stromatolites, and Thrombolites*). Microbialites are composed of trapped, bound, and/or precipitated sediment, and exhibit a range of mineralogies (Figure 1). This chapter focuses on carbonate microbialites, which are the most widespread and the most studied.

Microbialites are “rocks” that are produced, induced, or influenced by benthic microbial communities, primarily bacteria and sometimes also microeukaryotes, such as diatoms. These microbial communities are organized in mats or biofilms (e.g., Stolz, 2000), consisting of microscopic organisms enveloped in an organic matrix of extracellular polymeric substances (EPS; Decho, 1990; Bhaskar and Bhosle, 2005; see Chapter *Extracellular Polymeric Substances (EPS)*). Because the microbial mat is dominantly organic, it is rarely preserved in the fossil record. In some unusual cases, exceptional taphonomic conditions can preserve intact cells and even the EPS structure (e.g., silicification or preserved remnants of EPS matrices, Golubic and Hofmann, 1976; Barbieri et al., 2004; Barbieri and Cavalazzi, 2005; Altermann et al., 2006; Benzerara et al., 2006; Kumar and Pandey, 2008; Lepot et al., 2008). More commonly, the organic matter decomposes to carbon dioxide (CO₂) or methane (CH₄), although in some cases incomplete degradation can lead to organic matter enrichment of the sediment. Evidence of the original microbial mat or biofilm is generally indirect (e.g., specific sedimentary (bio)structure, micromorphology, organic biomarkers, and stable isotopic fractionation). Microbial mats can help preserve sedimentary structures in the fossil record (“microbially-induced sedimentary structures” – MISS; Noffke et al., 2003). The most

spectacular examples are carbonate microbialites. Examples of modern microbialites in the following section are followed by a discussion of processes of formation.

Types of modern microbialite

Microbialite descriptions incorporate a range of scales, from macrometers to micro/nanometers (e.g., Shapiro, 2000). Megastructure relates to the geographical extension of a microbial deposit and overall deposit morphology (e.g., ridges, biostrome, and bioherm). Macrostructure characterizes the morphology of an individual buildup (e.g., domal, branching, knobby). Mesostructure refers to structures visible with the naked eye, such as lamination. Microstructure is observed with a microscope, such as light, confocal, scanning electron (SEM), or transmission electron microscope (TEM).

Microbialite classification is based on mesostructure with four common types (Figure 2): laminated microbialites classified as stromatolites, thrombolites are clotted, leiolites are structureless, and dendrolites are dendritic (Burne and Moore, 1987; Riding, 1991, 2000; Dupraz and Strasser, 1999, 2002). All of these structures exhibit a wide range of microstructures including micropeloidal, densely micritic, or agglutinated microfabrics (Riding, 1991; Dupraz and Strasser, 1999). Three types of modern microbialites are described in the following section; dendrolites have not yet been found in modern environments. For further description of microbialite classification and microstructure see Chapter *Microbialites, Stromatolites, and Thrombolites*.

Stromatolite

The term stromatolite is derived from the Greek “stroma,” meaning mattress or stratum and “lithos,” meaning rock. The term was first introduced by Kalkowsky in 1908 to refer to “laminated benthic microbial deposits” (see also Riding, 1999; Chapter *Microbialites, Stromatolites, and Thrombolites*). The first modern stromatolites were found in the Shark Bay, Western Australia in 1954 in the hypersaline water of Hamelin Pool. Until this date, scientists believed that stromatolites were extinct, found only in the fossil record. Although the biogenicity of 3.5 Ga stromatolites has been questioned (Buick et al., 1981; Lowe, 1994; Grotzinger and Knoll, 1999; Lindsay et al., 2003), all modern microbialites called stromatolites are associated with microbial communities that induce, or serve as organic substrate for, precipitation (Riding, 2000). Modern stromatolites are found in many different locations including marine, hypersaline, freshwater, and even continental environments.

Open marine stromatolites

The Bahamas hosts the only known examples of open marine stromatolites. These structures are found at a variety of locations on the margins of Exuma Sound including Schooner Cays, Lee Stocking Island, Stocking Island Highborne Cay, and Darby Island (Dravis, 1983;

Carbonates

Calcite - CaCO_3
 Mg-Calcite - $(\text{Mg}_x\text{Ca}_{1-x})\text{CO}_3$
 Aragonite - CaCO_3
 Vaterite - CaCO_3
 Monohydrocalcite - $\text{CaCO}_3 \cdot \text{H}_2\text{O}$
 Protodolomite - $\text{MgCa}(\text{CO}_3)$
 Hydrocerussite - $\text{Pb}_3(\text{CO}_3)_2(\text{OH})_2$
 Amorphous forms - $\text{CaCO}_3 \cdot \text{H}_2\text{O}$ or CaCO_3

Phosphates

Octacalcium phosphate - $\text{Ca}_8\text{H}_2(\text{PO}_4)_6$
 Brushite - $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$
 Francolite - $\text{Ca}_{10}(\text{PO}_4)_6\text{F}_2$
 Carbonated-hydroxylapatite (dahllite) - $\text{Ca}_5(\text{PO}_4, \text{CO}_3)_3(\text{OH})$
 Whitlockite - $\text{Ca}_8\text{H}_2(\text{Mg, Fe})_2 + 2(\text{PO}_4)_4\text{I}_4$
 Struvite - $\text{Mg}(\text{NH}_4)(\text{PO}_4) \cdot 6\text{H}_2\text{O}$
 Vivianite - $\text{Fe}_3 + 2(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$
 Amorphous Calcium Phosphate (at least 6 forms) variable
 Amorphous Calcium Pyrophosphate - $\text{Ca}_2\text{P}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$

Sulfates

Gypsum - $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$
 Barite - BaSO_4
 Celestite - SrSO_4
 Jarosite - $\text{KFe}_3^{+3}(\text{SO}_4)_2(\text{OH})_6$

Sulfides

Pyrite - FeS_2
 Hydrotroilite - $\text{FeS} \cdot \text{nH}_2\text{O}$
 Sphalerite - ZnS
 Galena - PbS
 Hydrotroilite $\text{FeS} \cdot \text{nH}_2\text{O}$
 Sphalerite ZnS
 Wurtzite ZnS
 Greigite Fe_3S_4
 Mackinawite $(\text{Fe, Ni})_9\text{S}_8$
 Amorphous Pyrrhotite Fe_{1-x}S ($x = 0-0.17$)
 Acanthite Ag_2S

Arsenates

Orpiment - As_2S_3

Hydrated Silica

Amorphous Silica - $\text{SiO}_2 \cdot \text{nH}_2\text{O}$

Chlorides

Atacamite - $\text{Cu}_2\text{Cl}(\text{OH})_3$

Fluorides

Fluorite - CaF_2
 Hieratite - K_2SiF_6

Oxides

Magnetite - Fe_3O_4
 Amorphous Iron Oxide - Fe_2O_3
 Amorphous Mn Oxide - Mn_3O_4
 Amorphous Ilmenite $\text{Fe}^{+2}\text{TiO}_3$

Metals

Sulfur - S

Hydroxides and Hydrous Oxides

Goethite - $\alpha\text{-FeOOH}$
 Ferrihydrite - $5\text{Fe}_2\text{O}_3 \cdot 9\text{H}_2\text{O}$
 Lepidocrocite - $\gamma\text{-FeOOH}$
 Ferrihydrite - $5\text{Fe}_2\text{O}_3 \cdot 9\text{H}_2\text{O}$
 Todorokite - $(\text{Mn}^{+2}\text{CaMg})\text{Mn}_3^{+4}\text{O}_7 \cdot \text{H}_2\text{O}$
 Birnessite - $\text{Na}_4\text{Mn}_{14}\text{O}_{27} \cdot 9\text{H}_2\text{O}$

Organic Crystals following Lowenstam & Weiner (1989)

Whewellite - $\text{CaC}_2\text{O}_4 \cdot \text{H}_2\text{O}$
 Weddellite - $\text{CaC}_2\text{O}_4 \cdot (2+x)\text{H}_2\text{O}$
 Mn Oxalate - $\text{Mn}_2\text{C}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$
 Earlandite - $\text{Ca}_3(\text{C}_6\text{H}_5\text{O}_2)_2 \cdot 4\text{H}_2\text{O}$
 Glushinskite - $\text{MgC}_2\text{O}_4 \cdot 4\text{H}_2\text{O}$
 Manganese Oxalate - $\text{Mn}_2\text{C}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$
 Sodium urate - $\text{C}_5\text{H}_3\text{N}_4\text{NaO}_3$
 Uric Acid - $\text{C}_5\text{H}_4\text{N}_4\text{O}_3$
 Ca tartrate - $\text{C}_4\text{H}_4\text{CaO}_6$
 Ca malate - $\text{C}_4\text{H}_4\text{CaO}_5$
 Paraffin Hydrocarbon
 Guanine - $\text{C}_5\text{H}_3(\text{NH}_2)\text{N}_4\text{O}$

Microbialites, Modern, Figure 1 Nomenclature and chemical compositions of minerals produced by biologically-related mineralization processes. (Modified from Weiner and Dove, 2003; data from Lowenstam and Weiner, 1989; Simkiss and Wilbur, 1989; Mann, 2001; Weiner and Addadi, 2002.)

Microbialites, Modern, Figure 2 Descriptive terminology for microbialite macro-, meso, and microfabrics. (From Kennard and James, 1986; Riding, 1991; Schmid, 1996; Dupraz and Strasser, 1999; Shapiro, 2000.)

Microbialites, Modern, Figure 3 Underwater photograph showing shallow subtidal stromatolites (Darby Island, Bahamas) with a vertical section (upper left hand insert) showing well-developed lamination.

Dill et al., 1986; Reid et al., 1995). These stromatolites are coarse grained structures, composed of ooid sand; they form in intertidal and subtidal environments, exposed to high wave energy and strong tidal currents (e.g., Gebelein, 1976; Reid et al., 2000). Many of the stromatolites exhibit well-developed laminae (Figure 3; e.g., Reid et al., 2000). The lamination results from iterative growth of different types of microbial mats on the top of the build-ups (Figure 4). Each microbial mat forms a distinct mineral product, which can be recognized in thin section and SEM (Figure 5; Reid et al., 2000). The first mat type (1) is dominated by the filamentous cyanobacterium *Schizothrix*, which traps and binds ooids. The stickiness of the mat EPS results in the trapping of particles, which are subsequently bound by the upward growth of the cyanobacterial filaments. Other microorganisms (e.g., diatoms that produce copious amounts of EPS) can also participate in trapping grains. The second mat community (2) consists of a thin biofilm with abundant heterotrophic bacteria. Precipitation of aragonite within this biofilm forms a micritic lamina, which caps the underlying ooids. The third mat type (3) is characterized by an abundance of the endolithic coccoid cyanobacterium *Solentia* spp. *Solentia* tunnels through grains, leaving bore holes filled with EPS. Aragonite precipitation within the EPS results in micritization of the grains and, when tunnels cross between grains, welds the grains together. This process forms a well-cemented layer (Macintyre et al., 2000; Reid and Macintyre, 2000; Reid et al., 2000). The in situ precipitation of carbonate, which leads to early lithification of

the stromatolite-forming mats, is a result of prokaryotic activity (Visscher et al., 2000; Reid et al., 2003a).

Dominance of prokaryotic communities on the surfaces of modern marine stromatolites, is favored by the selective environmental pressure of periodic burial by sand (Andres and Reid, 2006; Kromkamp et al., 2007). In contrast to eukaryotes, which are typically killed when buried for periods of weeks to months, prokaryotes such as cyanobacteria are able to survive and recover from long burial events (Kromkamp et al., 2007). This attribute may contribute to the success of stromatolites in modern and past environments. Eukaryotic colonization (macroalgae: e.g., *Batophora*), during week- to month-long periods of exposure disrupts the lamination resulting from the cycling of prokaryotic mats, producing intervals of crude to no lamination within the stromatolite head.

It should be noted that trapping and binding alone does not form a stromatolite. The key factor in allowing development of a lithified laminated buildup is a hiatus in sediment accretion and corresponding development and lithification of a microbial biofilm. During long hiatus periods (i.e., several weeks), surfaces infested with the coccoid bacterium *Solentia* forms thicker, well-cemented lamina of fused ooid grains. Precipitation of aragonitic needles associated with the activity of sulfate-reducing bacteria is a key feature in carbonate precipitation within Bahamian stromatolites (Visscher et al., 2000). Precipitation resulting from anaerobic heterotrophic activity is supported by isotopic data (Andres et al., 2005).

Microbialites, Modern, Figure 4 (Continued)

Factors leading to the cycling of surface communities responsible for lamination in Bahamian stromatolites are currently under investigation (Andres and Reid, 2006). Both biological and environmental factors may be important (Figure 6; Seong-Joo et al., 2000; Reid et al., 2003a). Biological factors include microbial ecological interactions, and production and consumption of organic and inorganic compounds. Extrinsic factors include temperature, light, nutrients, and hydrodynamics, which could affect the stickiness of EPS and/or sediment supply (Figure 6).

Hypersaline and saline stromatolites

In contrast to open marine environments, where modern stromatolites are rare, living stromatolites are more common in hypersaline environments. This is because microbial communities are able to cope with high salinity, whereas most eukaryotes, such as macroalgae and burrowing/grazing invertebrates, which compete with or ingest cyanobacteria and disrupt lamination, are largely excluded (Fischer, 1965; Awramik, 1971, 1982, 1992; Walter and Heys, 1985; Riding, 2006).

Stromatolites in Shark Bay, Western Australia are the most famous stromatolites thriving in hypersaline water. They are found in the Hamelin Pool Marine Nature Reserve of the Shark Bay UNESCO World Heritage Site. Ranging from 55–70 ppt throughout the year (Playford, 1990), Hamelin Pool has approximately double normal marine salinity and hosts abundant and diverse stromatolites. Shark Bay stromatolites were discovered in 1954 by Johnstone, Playford, and Chase of the West Australian Petroleum Pty. Ltd (Playford and Cockbain, 1976). They were the first modern stromatolites discovered with sizes and shapes comparable to fossil counterparts (Logan, 1961; Logan et al., 1974; Playford and Cockbain, 1976; Playford, 1979; Bauld et al., 1979; Bauld, 1981; Burns et al., 2004). Like Bahamian stromatolites, Shark Bay structures are formed by both (1) microbial trapping and binding and (2) microbial precipitation. Both processes are important in the intertidal zone, forming coarse grained sandy stromatolites. Microbial precipitation is the primary accretionary mechanism in the subtidal zone of Shark Bay, forming muddy, micritic stromatolites (Reid et al., 2003b).

As a result of the dominant sandy textures of Shark Bay stromatolites and open marine stromatolites in the Bahamas, some authors have proposed that these stromatolites are not appropriate analogs for fossil stromatolites, which are generally display fine-grained, micritic microstructures (Awramik and Riding, 1988). Despite their overall coarse-grained texture, these modern stromatolites have micritic laminae formed as a result of microbially-induced precipitation (Reid et al., 2000; Visscher et al., 2000). Moreover, the ecological model developed for Bahamian stromatolites, in which lamination results from the cycling of prokaryotic communities on the stromatolite surface, is likely applicable to the growth of Shark Bay stromatolites. Indeed, a model of iterative accretion of laminae, which record both microbial and environmental fingerprints and progressively shape the emergent morphology, may serve as a conceptual model for the growth of fossil stromatolites.

In addition to Shark Bay, living stromatolites are also present in many other saline and hypersaline environments. Several saline lakes in Australia harbor stromatolites, including Lake Thetis, near Cervantes, lakes on Rottne Island (Reitner et al., 1996), and Lake Clifton near Mandurah (e.g., Grey et al., 1990). Cyanobacterial stromatolitic domes have been described in the intertidal zone of Bermuda (e.g., Sharp, 1969; Golubic and Focke, 1978) and small crudely laminated knobs have been found in a hypersaline lake on Bonaire Island in the Netherlands Antilles (Golubic and Focke, 1978). Various islands in the Bahamas also have hypersaline lakes with well-developed microbial mats and stromatolites, including Storr's Lake on San Salvador. Storr's lake harbors alternating stromatolitic and thrombolitic buildups (Mann and Hoffman, 1984; McNeese, 1988; Neumann et al., 1988; Mann and Nelson, 1989; Pentecost, 1989; Zabielski, 1991).

Fresh water and continental stromatolites

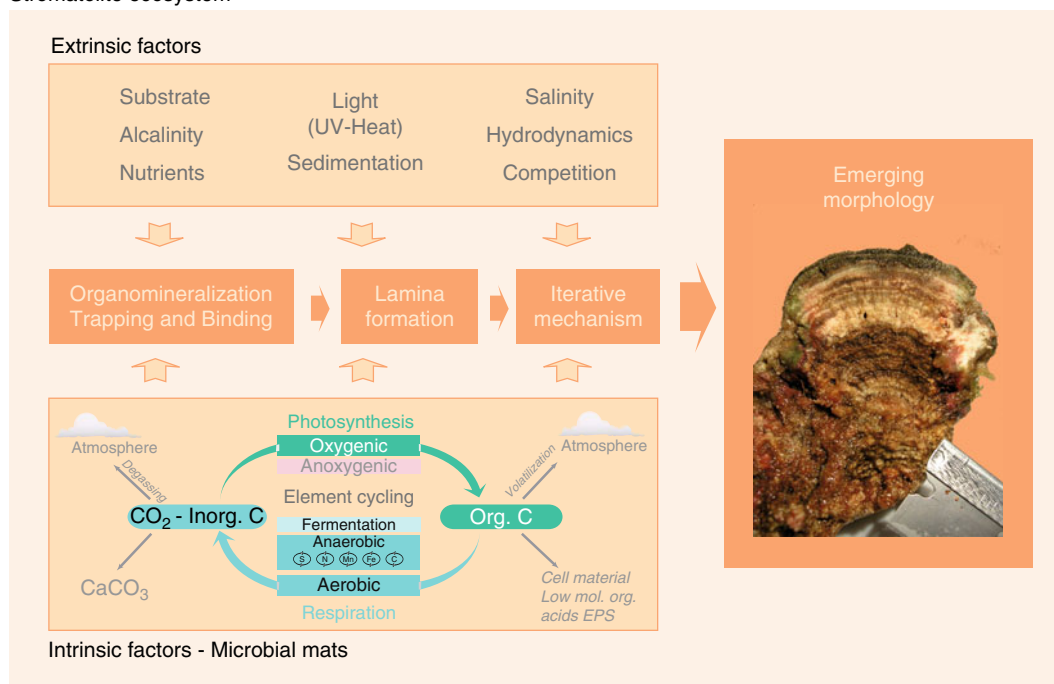

Numerous examples of freshwater laminated microbialite have been published. One of the most widespread examples of these microbialites is travertines. Tufa stromatolites (meteoene travertine following Pentecost (2005)) are freshwater fluviatile tufas, which locally exhibit thick laminated crusts formed by calcified cyanobacteria (Pentecost, 1978; Riding, 1991b, 2000). Most of the precipitation of carbonate in these travertines results from physicochemical

Microbialites, Modern, Figure 4 Model of coarse-grained open-marine stromatolite formation. (a) Cyanobacteria colonize and stabilize mobile ooid sand (trapping and binding). (b) A complex microbial mat develops in the upper few millimeters of the sediment (Cya cyanobacteria; SRB sulfate reducing bacteria; SOB sulfide oxidizing bacteria (aerobic and anaerobic); Het aerobic heterotrophs; see also Figure 8). (c–d) As a result of sediment accretion, the microbial mat migrates upward, continuing trapping and binding. Cyanobacteria (and heterotrophs) can survive massive burial. No significant in situ precipitation is observed at this stage, which corresponds to the Type 1 mat in Figure 5. (e) During a hiatus in sediment accretion, an EPS-rich biofilm develops, draping over the ooids (Type 2 mat, Figure 5). This biofilm rapidly lithifies due to the activity of anaerobic heterotrophs (i.e., SRB), forming a thin lamina of micritic aragonite (see Figure 5b4). (f) A prolonged hiatus in trapping and binding results in colonization of ooid grains under the biofilm by the endolithic cocoid cyanobacteria *Solentia* sp. (Type 3 mat, Figure 5) Precipitation of aragonite in the bore holes made by these endoliths destroys the internal microstructure of ooids, changing their color from golden brown to gray. Precipitation in bore holes crossing between grains fuses them together (Figure 5c2–4). Resumption of trapping and trapping corresponds to formation of a new Type 1 mat (e2, f2). The iterative succession of these three different mat types is responsible for the lamination observed in open-marine stromatolite (Figure 3).

Microbialites, Modern, Figure 5 Micrographs illustrating the main features of the surface mats responsible for the formation of modern marine stromatolites. Stromatolite lamination results from the iterative growth at the surface of the build up of three mat types: (1) Type 1 mats are dominated by filamentous cyanobacteria, which trap carbonate sand grains through EPS stickiness (A₁₋₄); (2) Type 2 mats consist of a continuous biofilm, draping the stromatolite surface (white arrows in B₁₋₃); the biofilm is composed of extracellular polymeric substances (EPS, B₃) containing numerous heterotrophic bacteria. This biofilm rapidly lithifies as a result of precipitation of aragonite needles within the biofilm (B₄); (3) Type 3 mats are characterized by endolith-infested ooid grains (yellow arrows in C₁₋₂), which appear gray and are fused together, below a surface biofilm. (A₁-B₁-C₁) binocular micrographs, (A₂-B₂-C₂) petrographic micrographs, (A₃-B₃-C₃) high vacuum scanning electron microscope images (SEM; chemical drying), and (A₄-C₃-C₄) cryo-SEM (frozen samples) images.

Stromatolite ecosystem

Microbialites, Modern, Figure 6 Interactive processes within the stromatolite ecosystem. Intrinsic (microbial mat-related) and extrinsic (environment-related) factors work together to determine the emergent stromatolite morphology and fabric, which can be described at microscale (biomineralization, trapping, and binding), mesoscale (laminae formation), and macroscale (iterative mechanism leading to morphology) levels.

degassing of CO₂ through resurgence, cascades, or waterfalls. Photosynthetic uptake of CO₂ by cyanobacteria can, however, be responsible for the precipitation of calcium carbonate in slow running and low DIC streams (Verrecchia et al., 1995; Merz-Preiss and Riding, 1999; Arp et al., 2001). Relatively low DIC and high Ca²⁺ concentration is required for photosynthesis to influence carbonate alkalinity and enable precipitation (Arp et al., 2001, 2003).

Fresh water stromatolites are also present in Antarctic lakes, which are permanently ice-covered (Parker et al., 1981). These lakes are seasonally fed by glaciers, which modify salinity from fresh-to-saline while oxygen levels vary from anoxic to supersaturated. The stromatolites are formed through sediment trapping and binding as well as carbonate precipitation in cyanobacterial-dominated (e.g., *Phormidium*, *Oscillatoria*) microbial mats. Other non-marine environments with stromatolites include alkaline lakes, such as the Caldera lakes of Niuafo'ou Island (Tonga), with spectacular laminated buildups (Kazmierczak and Kempe, 2006).

Laminated deposits, referred to as terrestrial stromatolites (Verrecchia et al., 1995; Riding, 2000), are observed in "non-water-saturated" environments. These deposits have also been called lichen stromatolites (Klappa, 1979) and subaerial stromatolites (Riding, 1991b). They consist of laminar calcretes formed by microbial activity or in close association with microbial communities.

Determining between biogenic and non-biogenic calcretes is often difficult as carbonate precipitation may be caused by physicochemical evaporation (e.g., Read, 1976), and/or cyanobacterial activity (e.g., Verrecchia et al., 1995).

Thrombolite

The term thrombolite was introduced by Aitken (1967) for microbial "structures related to stromatolites, but lacking lamination and characterized by a macroscopic clotted fabric". Since this initial definition, thrombolites and stromatolites have been recognized as two distinct microbialite structures (Kennard and James, 1986). The key microstructure of thrombolites is mesoclots, which produce the clotted fabric (Shapiro, 2000). The mesoclots consist of polymorphic (simple spheroids to polylobate), millimeter to centimeter-sized, aggregates which display a variety of forms, from simple spheroids to polylobate masses (e.g., Shapiro, 2000). Clotted mesostructures have been described for many fossil thrombolites, which are mostly composed of fine-grained carbonate. Therefore, many authors define mesoclots as mostly composed of micrite or micropeloids (Kennard, and James, 1986; Dupraz and Strasser, 1999; Shapiro, 2000). However, modern thrombolites, as well examples from the Miocene, show agglutinated, clotted fabrics (Riding, 2000). The mesoclots of modern thrombolites thus consist of micrite, micropeloids, or agglutinated particles (Figure 2).

The clotted fabric of thrombolites can have a variety of origins. The fabric can be attributed “to the in situ calcification of coccoid or coccoid-dominated microbial communities” (Kennard and James, 1986). Other mechanisms involve bioturbation and bioerosion, and thrombotic mesostructures within large Bahamian stromatolites are often due to disruption of the lamination by eukaryotic colonization (e.g., *Batophora* sp. and other algae).

In some cases, environmental conditions may trigger changes between thrombolite and stromatolitic fabrics. In Storr’s Lake (San Salvador, Bahamas), well-developed thrombolites alternate with stromatolitic layers (McNeese, 1988; Mann and Nelson, 1989). This alternation might be triggered by lake-level fluctuations and associated turbidity variability. This mechanism results in a succession of phototrophic-dominated (stromatolites) to heterotrophic-dominated communities (thrombolites) as surface communities, as modeled by Dupraz et al. (2006).

Many other modern lakes host thrombolite deposits: Lake Clifton, Lake Tethys, Lake Richmond and different lakes on Rottnest Island (Australia), Kelly and Pavillon lakes (British Columbia, Canada), lakes on Bonaire Island (Netherlands Antilles, southern Caribbean; Kobluk and Crawford, 1990), Lago Sarmiento (Patagonia, Chile), Poza Azul lake (Cuatro Ciénegas, Mexico), Yellow Stone National Park (USA), Green Lake (Fayetteville, New York, USA). In addition, travertines showing thrombotic features have been referred to as “Tufa Thrombolite” (Riding, 2000).

Leiolite

The term leiolite comes from the Greek word “leios,” meaning uniform or smooth and “lithos,” (meaning rock) and was originally applied to late Miocene (Messinian) deposits in Spain (Figure 2; Braga et al., 1995). Leiolite is characterized by relatively structureless, aphanitic, mesostructure, lacking lamination or clots, and can be a synonym for “cryptomicrobial” as used by Kennard and James (1986). Most authors tend to classify microbialites as either stromatolites or thrombolites, despite the fact that many of these deposits lack the defining mesostructures and would more appropriately be termed leiolite (see Riding, 2000). No examples of modern leiolite have been published. However, examples could include non-laminated, non-thrombotic portions of Bahamian or Shark Bay stromatolites, carbonate crust formation in hypersaline lakes (Dupraz et al., 2004), and biological stabilization of sand dune by chasmolithic microorganisms (Hillgaertner et al., 2001).

Other types of microbialites

Microbial processes or the presence of microbes are often intimately related to sedimentary processes in modern carbonate systems, although the resulting deposits may not be considered as true microbialite and classified as stromatolite, thrombolite, or leiolite. These microbial carbonate

deposits include meteogene and thermogene travertine (Pentecost, 2005), where microbial influence creates specific microfabrics. Spectacular examples of travertines can be observed in many alkaline lakes, forming carbonate towers (e.g., Pyramid Lake, Nevada (Benson, 1994)), Lake Can, Turkey (Kempe et al., 1991), and Mono Lake, California (e.g., Bischoff et al., 1993; Riding, 2000). Carbonate chimneys are also formed in hydrothermal systems, where microbial activity is important (e.g., “Lost City” Hydrothermal Field; Kelley et al., 2001; Ludwig et al., 2006).

Other deposits that are difficult to classify include microbial calcrete – a terrestrial carbonate the formation of which is strongly influenced by bacteria and fungi (Jones and Wilson, 1986; Wright et al., 1988; Verrecchia and Verrecchia, 1994; Verrecchia et al., 1995). In addition, in continental environments, the formation of needle fiber calcite (NFC) is related to fungi activity (Verrecchia and Verrecchia, 1994; Cailleau et al., 2004, 2005). Mondmilch or Moonmilch – a soft paste-like or powdery cave deposit – includes important microbial populations, which influence precipitation (Thraillkill, 1976; Canaveras et al., 2006). Microbial mats are also involved in the formation of oncoids, which are unattached spherical stromatolites (e.g., Bathurst, 1966), and microbial activity may play a role in the formation of “whittings” (Thompson, and Ferris, 1990; Robbins, and Blackwelder, 1992).

Processes of microbialite formation

Early lithification is a key process in the formation of modern carbonate microbialites and is critical for the preservation of these structures in the fossil record. Lithification processes start at the time of deposition and continue during burial (diagenesis). Lithification consists of in situ precipitation of minerals, which progressively cement trapped grains (if present), and preserve the biosedimentary structures. Two closely coupled components are fundamental in carbonate precipitation within microbial mats: (1) the alkalinity engine and (2) the organic matrix in which this mineral is forming.

The alkalinity engine

The precipitation of carbonate minerals depends on the availability of carbonate ions, specific cations (e.g., Ca^{2+} , Mg^{2+}), and suitable nucleation sites. Carbonate minerals may precipitate when a solution is saturated with respect to that mineral. The degree of saturation is calculated via the saturation index of the specific mineral:

$$\text{SI} = \log(\text{IAP}/K_{\text{ps}}) \quad (1)$$

IAP is the “ion activity product” and K_{sp} is the solubility product of the corresponding mineral (solid phase). In the case of CaCO_3 , both the carbonate alkalinity and the activity of the available cations are taken into account

when calculating the saturation index (Stumm and Morgan, 1996):

$$SI_{\text{CaCO}_3} = \text{Log}(\{ \text{Ca}^{2+} \} * \{ \text{CO}_3^{2-} \} / K_{\text{sp}}). \quad (2)$$

The activity of a given chemical compound corresponds to the concentration of that compound multiplied by the activity coefficient. The solubility products for aragonite and calcite are $10^{-6.19}$ and $10^{-6.37}$, respectively, at 25°C, 1 bar atmospheric pressure and 35 PSU salinity (Zeebe and Wolf-Gladrow, 2001). A solution is supersaturated with respect to a given mineral when SI is greater than 0, meaning that K_{sp} is smaller than IAP. Experimental evidence showed that a supersaturation must be greater than 0.8 in order to have spontaneous precipitation of CaCO_3 (Kempe and Kazmierczak, 1994). Arp et al. (2001) used SI greater than 1 (i.e., a 10-fold supersaturation) as a prerequisite for carbonate precipitation in non-marine environment.

Carbonate ion activity, $\{ \text{CO}_3^{2-} \}$, depends on the carbonate equilibrium. CO_2 dissolves in water to form carbonic acid (H_2CO_3). The amount of dissolved CO_2 is proportional to the partial pressure of CO_2 ($p\text{CO}_2$) in the gas phase in contact with the liquid (i.e., Henry's Law). This value varies with pressure and temperature. Low temperature and high pressure allow for more CO_2 dissolution in water. Carbonic acid is weak acid that will only partially dissociate in an aqueous solution to produce H^+ ion and the conjugate base. It will deprotonate as follows (with pK_s value for fresh water):

The two pK_s values vary as a function of the salinity. For seawater conditions, pK_{a1} and pK_{a2} are 5.9 and 8.9, respectively (at 25°C, 1 bar atmospheric pressure and 35 PSU salinity; Zeebe and Wolf-Gladrow, 2001).

Availability of carbonate ions is a prerequisite for precipitation of carbonate minerals. The amount of bicarbonate and carbonate ions in solution denotes carbonate alkalinity, which is a part of total alkalinity, including borate, hydroxide, phosphate, and silicate. In marine and most of freshwater environments, phosphate and silicate are minor components, and the carbonate equilibrium typically drives global alkalinity. Various processes can have an impact of carbonate alkalinity, indirectly promoting precipitation or dissolution of carbonate mineral. The sum of processes that creates alkalinity represents the “alkalinity engine.” This engine is intrinsically driven when alkalinity is affected by microbial communities, or extrinsically driven when physico-chemical processes of the macro-environment cause alkalinity shifts (Figure 7).

Intrinsic alkalinity engine (metabolism)

The way microbial communities acquire their energy and their source of carbon (i.e., through metabolism) can have a strong impact on local carbonate alkalinity. In a simplified view of the microbial carbon cycle, the production of organic matter through photosynthesis (oxygenic or anoxygenic) is coupled with the oxidation of organic carbon by aerobic (oxygen as oxidant) or

Microbialites, Modern, Figure 7 Model of carbonate precipitation within biofilms. Increases in alkalinity leading to precipitation can be (a) intrinsic, resulting from microbial metabolism or (b) extrinsic, resulting from environmental factors (b). In both the cases, the EPS matrix, which embeds the microbial communities, has a pivotal role in determining mineral morphology, composition, and mineralogy.

Microbialites, Modern, Figure 8 Model of microbial mat formation by the five main guilds (van Gernerden, 1993). (a) Typical diffusion of O₂ through the water-sediment interface in the absence of microbial activity. (b) Cyanobacteria colonize the sediment, fixing (reduce) CO₂ to form biomass using solar energy (photosynthesis) and using water as electron donor. O₂ is a byproduct (visible in the upper millimeter of the depth profile). (c) The autotrophically-produced organic carbon is degraded by aerobic heterotrophs (aerobic respiration) using O₂ as final electron acceptor. The consumption of oxygen results in, or is reflected by, a sharper O₂ gradient in the sediment (arrows) and the formation of an anoxic zone below the active cyanobacterial layer. (d) Anaerobic heterotrophs then develop in the anoxic zone (mostly SRB in this example). (e) SRB produces sulfide compounds, which can then feed anoxygenic photosynthesis and aerobic sulfide oxidation. (f) Examples of a hypersaline mat from the Bahamas showing classical zonation of bacterial guilds.

anaerobic (SO₄²⁻, NO₃⁻, Fe³⁺, etc. as oxidant) respiration (Figure 8). Most microbial metabolites (products of metabolism) are efficiently recycled within the mats, completely closing the cycles of major elements. Many microbial mats function as light-driven engines, fueled only by sunlight.

The biogeochemical niche of microorganisms can be described through three overarching metabolic characteristics related to energy generation and biomass acquisition: the energy source, the electron donor used for energy generation, and the carbon source for biomass production. Each of these three properties have two possibilities: potential energy sources are light (photo-) or chemical redox reactions (chemo-), electron donors can be organic (organo-)

or inorganic (litho-), and biomass can be derived from CO₂ fixation (autotrophy) or from carbon that is already fixed (heterotrophy). For example, a cyanobacterium derives energy from light (photo) uses water as electron donor (litho) and fixes CO₂ for biomass (auto-); it is hence designated as a photolithoautotroph (trophos means “to feed”). A typical aerobic bacterium that uses organic carbon is a chemoorganoheterotroph, etc.

Different types of metabolism impact carbonate precipitation and dissolution by taking up (autotrophy) or releasing (respiration) CO₂ and through production or consumption of organic acids. Changes in organic acid concentrations modify alkalinity and pH of the mats (Ehrlich, 1996; Visscher and Stolz, 2005). Mechanisms

that can promote precipitation of carbonate minerals include the following:

1. *Oxygenic photosynthesis* (producing O_2) by cyanobacteria (photolithoautotrophy). Uptake of CO_2 during photosynthetic activity leads to precipitation of carbonate in the sheath or in the direct vicinity of the cyanobacteria (Pentecost and Riding, 1986; Frey et al. and Verrecchia, 1998, 1999; Merz-Preiss and Riding, 1999; Riding, 2000) (Figure 9). The increase in alkalinity is attributed to an exchange of HCO_3^- and OH^- through the cell membrane (Figure 9). Photosynthesis is an important mechanism for microbialite formation in freshwater environment (Arp et al., 2001), where it may help overcome the kinetic barrier for $CaCO_3$ precipitation, even in highly supersaturated freshwater settings (Shiraishi et al., 2008).
2. *Aerobic respiration* (chemoorganoheterotrophy) generally dissolves calcium carbonate through production of CO_2 . However, precipitation can occur in a well-buffered alkaline environment when CO_2 produces carbonate ions. Carbonate minerals can also be formed when aerobic respiration consumes strong organic acids and produce CO_2 that will be degassed. This process is proposed for carbonate precipitation in tropical soil associated to the oxalate-carbonate cycle (Braissant et al., 2004). In the absence of O_2 , some bacteria can generate energy through fermentation, which process uses the same compound (e.g., organic carbon, inorganic sulfur) both as electron donor and acceptor. Most fermentation of organic carbon will lead to dissolution of carbonate (Visscher and Stolz, 2005).
3. *Anaerobic respiration*: certain bacteria can oxidize organic matter using respiratory chains that do not use O_2 as final electron acceptor (also chemoorganoheterotrophy). These bacteria can use, e.g., sulfate (sulfate-reduction), nitrate (nitrate-reduction), iron (iron-reduction), manganese (manganese reduction), or even HCO_3^- . These types of metabolism can promote precipitation of carbonate through various processes (e.g., Visscher and Stolz, 2005): consumption of organic acid, production of base (e.g., NH_3), removing precipitation inhibition (removing of SO_4^{2-}), etc. Sulfate reduction is the main process in marine environment due to high concentration of SO_4^{2-} in seawater.
4. *Chemolithoautotrophy*: Some bacteria do not oxidize organic matter to generate energy. They will instead use the chemical energy (chemo) produced by the oxidation of inorganic (litho) electron donors such as H_2 , CO , Fe^{2+} , NH_4^+ and HS^- in order to fix CO_2 (autotrophy). Sulfide (in sediments) and ammonium (in the water column) oxidation are the most abundant chemolithoautotrophic electron donor in marine environment. Aerobic sulfide oxidation and ammonium oxidation is likely to induce dissolution of carbonate minerals, whereas anaerobic sulfide oxidation (e.g., using nitrate as electron acceptor) may induce

precipitation (Visscher and Stolz, 2005). However, most of these types of metabolism are all autotrophic, i.e., fixing CO_2 . The uptake of CO_2 can increase carbonate alkalinity and induce precipitation of carbonates in similar way that physicochemical degassing of CO_2 does.

Extrinsic alkalinity engine

The determination of alkalinity-driving forces that form microbialites is generally a complex task. In many cases, a combination of intrinsic and extrinsic factors is responsible for precipitation. There are however, a few examples where the macroenvironment acts as a major player in microbial mat lithification. The two important physicochemical processes that can lead to carbonate precipitation in microbial mats are water evaporation and CO_2 degassing. Even in these cases, however, the microbial communities of the mats can serve as substrates for physicochemical carbonate precipitation and affect mineral mineralogy or morphology.

In the marine environment, solar evaporation of water may lead to the formation of evaporitic minerals (e.g., Warren, 2006). Although a variety of carbonate minerals can be produced through this mechanism (e.g., calcite, ikaite, aragonite, Mg-calcite, dolomite, and magnesite), evaporites largely consist of halite and gypsum. Examples of microbial mats associated with gypsum deposits have been described (e.g., Babel, 2004). Moreover, bacteria trapped in gypsum crystals are able to survive for millions of year (Vreeland et al., 2000, 2007). The specific role of microbes in gypsum nucleation is, however, not clear as the evaporation processes generally obscure microbial signatures. For reviews on evaporites, see Yechieli, and Wood (2002) or Warren (2006).

Precipitation of carbonate can also result from degassing of CO_2 and forms travertines. Travertines represent chemically-mediated continental carbonate deposits that form around sinter sources along streams and lakes (Pentecost, 2005). The precipitated minerals, consisting of aragonite or calcite, are mainly related to the release of CO_2 from the system, resulting in supersaturation with respect to calcium carbonate. This can be illustrated by the buffering equation of the carbonate:

Removal of CO_2 through degassing will drive this equation to the right, promoting precipitation of $CaCO_3$. Similarly, increasing dissolved CO_2 drive the equation to the left, resulting in dissolution of calcium carbonate.

Travertines can be classified based on the source of the CO_2 that is degassed (Pentecost, 2005). "Metogene travertines" are formed by degassing of meteoric carbon dioxide, whereas "thermogene travertines" are formed by the degassing of hydrothermal CO_2 . In metogene travertines, the CO_2 can originate from the atmosphere or from the soil-zone. In thermogene travertines, the bulk of the CO_2

Microbialites, Modern, Figure 9 Role of photosynthesis in the precipitation of carbonate minerals. (a) Photomicrograph of *Microcoleus* spp., a filamentous cyanobacterium showing the trichoma (chains of cells) embedded in a sheath. (b) Longitudinal section through a freshwater travertine (Sarine River, Switzerland) showing precipitation of CaCO_3 in the sheath of the filamentous cyanobacteria *Oscillatoria* sp. and *Phormidium* sp. (c) Perpendicular section through the same travertine. (d) Model of photosynthetically-driven carbonate precipitation. CO_2 dissolve in water, forming bicarbonate ions (the most common form of DIC between pH 5 and 9). The bicarbonate is taken up by cells of the trichoma; the enzyme carbonic anhydrase inside the cells produces CO_2 (used for photosynthesis) and OH^- . The release of hydroxyl ions outside the trichoma increases the alkalinity in the surrounding area of the cyanobacteria and induces precipitation of CaCO_3 (provided Ca^{2+} ions are available).

EPS alteration
leading to precipitation of carbonates

Biologically-induced mineralization

Biologically-influenced mineralization

Extrinsic Supersaturation of EPS

Forcing of mineralization on the EPS matrix.

Organic matrix and kinetic of precipitation can control mineral morphology.

Intrinsic Supersaturation of EPS:

Steric Hindrance

Changes in availability of functional groups (steric hindrance).

Cation binding capacity does not reflect abundance of functional groups

Microbialites, Modern, Figure 10 Mechanistic role of the organic EPS matrix in microbial mat lithification. The exopolymeric substances are produced by various groups of bacteria (especially cyanobacteria). EPS can bind large amounts of cations (i.e., Ca²⁺), reducing the calcium carbonate saturation index, inhibiting precipitation. Alteration of the EPS matrix can end this inhibition, allowing carbonate precipitation to commence. EPS alteration is achieved via two main pathways: (1) EPS degradation, and (2b) intrinsic supersaturation of the EPS binding capacity (modified from Dupraz and Visscher, 2005).

originates from thermal processes. These hydrothermal systems are commonly associated with region of recent volcanic or tectonic activities. It is important to note that the term travertine has variable usage in the literature. Many authors use travertine only for hot water deposits, using “tufa” for cold-water deposits (Pedley, 2000). Other authors use tufa for actively-forming deposits and travertine for non-active, fossil forms (see Chapter *Tufa, Freshwater*).

Although carbonate precipitation in travertines and tufas is driven by abiotic processes, precipitation often initiates on organic substrates, e.g., leaves, woods, algae, or microbial mats. In these cases, mineralogy and morphology are strongly influenced by the organic matrix (e.g., Fouke et al., 2000; Farmer, 2000; Pentecost, 2005; Turner and Jones, 2005). Microbial mats at hot springs, for example, can therefore have a profound impact on thermogene travertine by providing templates for mineralization, even though precipitation is due to vigorous CO₂ degassing (Farmer, 2000; Fouke et al., 2000). Travertine formation is thus an example of biologically-influenced mineralization, since the carbonate precipitation is not due to biological activity, but microorganisms indirectly affect the characteristics of the resulting minerals.

The organic matrix (EPS)

Microbial communities generally produce extracellular polymeric substances (EPS; see Chapter *Extracellular Polymeric Substances (EPS)*). This organic matrix is an important part of the microbial mat, preventing desiccation, retaining essential nutrients, protecting against UV radiation, and providing water channels for transport of metabolites and signaling compounds (Decho, 1990, 2000). Cyanobacteria are often considered to be the major producers of EPS. However, many other bacteria can produce EPS matrix, including aerobic and anaerobic (chemoorgano)heterotrophs, anoxygenic phototrophs, and chemolithoautotrophs (De Philippis et al., 1998, 2001; Stal, 2000, 2003; Richert et al., 2005). Anaerobic bacteria, especially sulfate-reducing bacteria, which play a key role in carbon metabolism in marine microbial mats (Thode-Andersen, and Jorgensen, 1989; Canfield and DesMarais, 1991; Visscher et al., 1991), are known to produce large amounts of EPS (Bosak and Newman, 2005; Braissant et al., 2007).

The EPS matrix is generally the location where the carbonate minerals nucleate and grow (Dupraz et al., 2004). EPS contains negatively-charged acidic groups (e.g., carboxyl, sulfhydryl, amine, hydroxyl groups), which can bind a large amount of mono- and divalent cations, notably Ca²⁺ (Braissant et al., 2007). This binding capacity may inhibit the precipitation of carbonate minerals by depleting calcium from the surrounding microenvironment (Figure 10). The saturation index of calcite depends on the carbonate alkalinity and the availability in calcium. Even if carbonate ions are in solution, the lack of free Ca²⁺ may inhibit precipitation (Dupraz and Visscher, 2005). Therefore, the physicochemical properties of the polymer

matrix, such as the acidity or composition of the functional groups associated with the EPS, are key factors in the formation of modern microbialites.

In order to precipitate calcium carbonate in microbial mats, the Ca²⁺-binding capacity of the EPS has to be reduced. Various mechanisms have been proposed (e.g., Dupraz and Visscher, 2005), which can be grouped into two main processes (Figure 10): (1) degradation of the EPS matrix and (2) intrinsic or extrinsic supersaturation of cation-binding sites (e.g., Dupraz and Visscher, 2005). As EPS is a sugar polymer, it serves as metabolic substrate for (chemoorgano) heterotrophic bacteria. Depolymerization (hydrolysis) of EPS, possibly by fungi and heterotrophs, including spirochetes (Harwood and Canale-Parola, 1984; Weaver and Hicks, 1995), must occur before sugar monomers are available. Microbial degradation of EPS liberates the calcium and produces inorganic carbon (under alkaline conditions, the dominant species is carbonate ion). Alternatively, if the amount of Ca exceeds the number of binding sites in the EPS, free calcium will be present and available for precipitation. These conditions can be achieved through extrinsic factors (the environment) through continuous input of Ca. It can also result from the steric hindrance of acidic groups within the EPS. Although EPS may indeed possess abundant functional groups capable of binding Ca²⁺ or Mg²⁺ ions, these groups may be “sterically-inhibited” (i.e., blocked) via molecular-scale interactions into a structurally complex EPS (Figure 10).

Summary

Microbialites are “organosedimentary deposits that accrete as a result of a benthic microbial community, which traps and binds sediment and/or forms the locus of mineral precipitation” (Kennard and James, 1986). Living examples of these structures can be found in many modern environments including marine, hypersaline, freshwater, and even continental settings. Microbialites are classified based on mesostructure as stromatolites (laminated), thrombolites (clotted), and leiolites (structureless). Among the most spectacular examples are modern stromatolites, which were first discovered in a hypersaline lagoon of Shark Bay in 1954. The only known examples of stromatolites presently forming in open marine environments are in the Bahamas. Lamination in these coarse-grained structures results from the iterative growth of three different types of microbial mats on the surfaces of the build-ups. These microbial communities are responsible for successive “trapping and binding” of sediment (type 1) and in situ precipitation of calcium carbonate (types 2 and 3). Both processes are essential for stromatolites formation. Modern thrombolites and leiolites are less well-studied than modern stromatolites.

Early lithification is a key process in the formation of modern microbialites. Lithification consists of in situ precipitation of minerals, which preserves the biosedimentary structures. Two key and closely coupled components

involved in carbonate precipitation within microbial mats are (1) the alkalinity engine and (2) the organic matrix. The alkalinity engine, which effectively changes the saturation index, is *intrinsically driven* when microbial metabolism is the dominant process causing carbonate precipitation. The alkalinity engine is *extrinsically driven* when the macroenvironment is responsible for microbial mat lithification. In both the cases, the organic matrix of extracellular polymeric substances (EPS), which embed the microbial communities, is the physical location where carbonate minerals nucleate and grow. Fresh EPS contains negatively-charged acidic groups, which bind large amount of cations (e.g., Ca^{2+}), inhibiting CaCO_3 precipitation. In order to precipitate carbonate, this inhibition has to be reduced by degradation of the EPS or by oversaturation of the cation-binding capacity. Microbial activity is ultimately responsible for EPS production and degradation leading mineral precipitation.

Microbialite Definition

Microbialites are “organosedimentary deposits that have accreted as a result of a benthic microbial community trapping and binding detrital sediment and/or forming the locus of mineral precipitation” (Burne and Moore, 1987, pp. 241–242).

Introduction

Microbial carbonates are produced by the interaction of microbial growth and metabolism, cell surface properties, and extracellular polymeric substances (EPS) with mineral precipitation and grain trapping. The early lithification that is essential for the accretion and preservation of benthic microbial carbonates is both biologically mediated and environmentally dependent. Consequently, microbialite history reflects not only microbial mat evolution, but also long-term changes in seawater and atmospheric chemistry that have influenced microbial metabolism and seawater carbonate saturation state.

Microbialites are in place benthic sediments produced by microbial processes. The term “microbialite” has been most widely used to describe carbonate stromatolites, thrombolites, and similar structures that occur as domes and columns in the shallow waters of lakes and seas, but it can also apply to many additional authigenic accumulations in which microbes are locally conspicuous, such as

some tufa, travertine, speleothem and spring, seep, and vent deposits. A series of terms and definitions were proposed between 1967 and 1987 in attempts to distinguish benthic sediments formed by microbial sediment trapping and/or precipitation. The first term, *cryptalgal*, was proposed by Aitken (1967, p. 1163) for rocks or rock structures “believed to originate through the sediment-binding and/or carbonate precipitating activities of non-skeletal algae.” The second was redefinition of *stromatolite* by Awramik and Margulis’ (1974) as “organosedimentary structures produced by sediment trapping, binding and/or precipitation as a result of growth and metabolic activity of organisms, primarily blue-green algae.” Both Aitken (1967, p. 1163) and Awramik and Margulis (1974) used blue-green algae to indicate cyanobacteria, and therefore Kennard and James (1986, p. 496) replaced *cryptalgal* by *cryptomicrobial*. The third term was *microbialite* (Burne and Moore, 1987), which effectively repeated Awramik and Margulis’ (1974) definition of *stromatolite*, thereby broadening its scope. The primary focus of all these definitions was stromatolites and thrombolites.

Research during the 1900s revealed many details concerning the nature and history of stromatolites, but it also led to nomenclatural uncertainty as it became necessary to accommodate newly recognized deposits, such as thrombolites. Aitken (1967, p. 1164) sought to clarify use of “algal” in carbonate rock descriptions by distinguishing “rocks composed of the remains of skeletal calcareous algae . . . from those formed by noncalcareous blue-green . . . and green . . . algae.” He termed the latter *cryptalgal*, defined as rocks or rock structures “believed to originate through the sediment-binding and/or carbonate-precipitating activities of nonskeletal algae” (Aitken, 1967, p. 1163). Aitken (1967, Fig. 1) regarded both thrombolites and stromatolites as *cryptalgal* deposits, distinguishing by their respective clotted and laminated macrofabrics. However, Awramik and Margulis’ (1974) proposed a broader definition of *stromatolite* as “megascopic organosedimentary structures produced by sediment trapping, binding and/or precipitation as a result of growth and metabolic activity of organisms, primarily blue-green algae.” This therefore subsumed thrombolite as a category within *stromatolite*.

As a result of these and other developments, by the 1980s stromatolites could variously be regarded as (1) microbial and laminated (e.g., Kalkowsky, 1908; Hofmann, 1969; Krumbein, 1983), (2) microbial but not necessarily laminated (Awramik and Margulis, 1974), and (3) laminated but not necessarily organic (Semikhatov et al., 1979) (see Riding, 1999, p. 324). Since the wording of Burne and Moore’s (1987, pp. 241–242) definition of *microbialite* closely followed that of Awramik and Margulis’ (1974) definition of *stromatolite*, it therefore required return to a narrower definition of *stromatolite*, as layered or laminated structures. This relatively narrow definition was intended by Kalkowsky (1908) and is implied by his term *stromatolith*; *stromat*, Greek for “to spread out,” suggests a layer. Burne and Moore’s

(1987) new term, *microbialite*, encompassed more diverse benthic microbial deposits. The outcome of these developments was that *stromatolite* and *thrombolite* could be considered as equal categories within *microbialite*, mirroring Aitken’s (1967, Fig. 1) classification of *stromatolites* and *thrombolites* within *cryptalgal* carbonates. Subsequently, these and other varieties of *microbialite* have commonly been distinguished by their dominant internal macrofabric: *stromatolite* (laminated), *thrombolite* (clotted), *dendrolite* (dendritic), and *leiolite* (aphanitic) (Riding, 2000, pp. 189–195) (Figure 1).

Given the importance of stromatolites in the development of these concepts, this orderly arrangement of terms under the *microbialite* umbrella relied heavily on stromatolites being microbial structures. However, as soon as Kalkowsky’s (1908) article was published, researchers began to point out similarities between stromatolites and abiogenic precipitates (Reis, 1908; Bucher, 1918), and this chorus has continued ever since. Logan et al. (1964, p. 69) suggested recognition of “inorganic stromatolites”; Hofmann (1973, Fig. 5) showed the difficulty of distinguishing stromatolites from other laminites; and Semikhatov et al. (1979, p. 994) proposed a descriptive rather than purely genetic definition of *stromatolite*. Reports of essentially abiogenic stromatolites have persisted, especially in the Proterozoic (Grotzinger and Read, 1983; Grotzinger, 1989a; Pope et al., 2000). Attempts to separate abiogenic and biogenic stromatolites are obstructed by *hybrid stromatolites* (see below, *Stromatolites*) consisting of millimetric alternations of abiogenic crust and lithified microbial mat (Riding, 2008). Consequently, although microbial mat models seem to apply well to all or most thrombolites, dendrolites and leiolites, they do not account for all stromatolite-like deposits, particularly in the Precambrian. The implications of this complication for stromatolite interpretation as well terminology have still to be worked out.

Microbialites in space and time

Microbes occupy a very broad range of environments, including waters of widely differing chemistry and composition, and their involvement in sedimentation is equally varied. Most microbialites are carbonate (e.g., aragonite, calcite, dolomite) in composition, but siliceous, phosphatic, iron, manganese, and sulfate examples also occur. The microbes in microbialites are dominantly bacteria, including cyanobacteria, together with small algae. From the perspective of biocalcification, *microbialite* carbonates are bioinduced. Bacteria in general exert relatively weak control over the organic site and mineralogy of calcification, and present-day microbial carbonates appear to be most widespread in environments where precipitation is inorganically favored. This environmental dependence means that where rapid cooling and degassing strongly favor mineral precipitation irrespective of organic intervention, as in hot water springs and vents, the overall sedimentary contribution of microbes may be

Microbialites, Stromatolites, and Thrombolites, Figure 1 Microbial carbonates defined by macrofabric: leiolite (aphanitic), stromatolite (laminated), thrombolite (clotted), dendrolite (dendritic). Examples show domes and associated sediment. Not to scale. All categories are integrational. In addition to domes/mounds, overall shape can include columns, layers, and irregular masses. A complication is that leiolite and stromatolite macrofabrics are defined by features within (i.e., internal to) the microbial carbonate, such as lamination. In contrast, thrombolite and dendrolite macrofabrics are defined by the external shape of individual masses of microbial carbonate, such as clots or small shrub-like masses. Thrombolitic stromatolite (Aitken, 1967), typified by some Shark Bay columns, is internally weakly clotted and crudely laminated. It is essentially agglutinated, in contrast to Neoproterozoic and early Palaeozoic thrombolites with calcified microbial microfabrics. In the latter, the clots may be prostrate and irregular, and also vertically extended into amalgamated elongate branches (e.g., *Favosamacteria*).

relatively minor. In such cases, they influence the fabric more than the process of deposition. In contrast, where waters are less saturated for minerals, microbial activity can play a major role in sediment precipitation. These differing roles are reflected in the form and fabrics of the resulting deposits.

Sensitivity to environmental influence is also reflected in the secular distribution of microbialites. Without ruling out the influence of other factors – such as competition with other organisms – marine microbial carbonate abundance through time significantly reflects fluctuation in carbonate saturation state (Fischer, 1965; Grotzinger, 1990; Riding and Liang, 2005). Microbial carbonates can therefore be relatively sensitive proxies for seawater carbonate chemistry, and for atmospheric composition, since cyanobacterial sheath calcification is promoted by increased bicarbonate uptake (Merz, 1992) when CO_2 levels decline (Riding, 2006).

Scope

The term microbialite, with its emphasis on benthic microbial deposits, encompasses a wide range of sediments; what does it not cover? “Benthic” would seem to exclude both allochthonous and interstitial microbial sediments.

If so, then biogenic “whiting” deposits produced by photo-synthetically induced nucleation of small CaCO_3 crystals in the water column are not microbialites, and neither are diagenetic bacterially induced precipitates such as cements and concretions. However, these somewhat artificial distinctions could be blurred, as in some soil crust and beachrock deposits. On the other hand, “microbial” must exclude abiogenic stromatolites, identified in both Precambrian and Phanerozoic sediments (Grotzinger and Read, 1983; Pope et al., 2000). This is a complication, especially since microbialite (Burne and Moore, 1987) is based on a preexisting definition of stromatolite proposed by Awramik and Margulis (1974), and arose from a need for a general term to encompass stromatolite, thrombolite, and related deposits. Such difficulties of definition should be resolved by increased understanding of both present-day and ancient examples of these important and geologically widespread deposits.

Stromatolites

Definition

Stromatolites are laminated benthic microbial deposits (Riding, 1991).

Introduction

Kalkowsky (1908) proposed the term stromatolite (*Stromatolith*) for columns and domes in early Triassic playa lake oolites, but similar structures were already long known from examples such as those in the late Cambrian of New York State that Steele (1825, pp. 17–18, pl. 2) described as “calcareous concretions” and Hall (1883) named *Cryptozoon* (Figure 2). The search for present-day analogs of these ancient stromatolites led from freshwater tufa (Walcott, 1914; Roddy, 1915) and marsh deposits (Black, 1933) to marginal marine domes (Ginsburg et al., 1954) and columns (Logan, 1961). These discoveries strongly supported Kalkowsky’s (1908) inference that stromatolites are essentially microbial deposits. But optimism that they could provide appropriate analogs for all ancient marine stromatolites was tempered by studies of Precambrian examples that include significant abiogenic precipitated components (e.g., Serebryakov, 1976, p. 633; Grotzinger and Knoll, 1999, p. 314). Some definitions of stromatolite have therefore encompassed both microbial and abiogenic layered/laminated authigenic crusts that characteristically form domical and columnar morphologies.

Definitions of stromatolite range from that of Kalkowsky (1908) to that of Semikhatov et al. (1979, p. 993): “a stromatolite is . . . an attached, laminated, lithified, sedimentary growth structure, accretionary away from a point or limited surface of initiation. Although characteristically of microbial origin and calcareous composition, it may be of any origin, composition, shape, size, or age.” Understanding of Kalkowsky’s view has been hindered by a definition incorrectly attributed to him by Krumbein (1983, p. 499): “stromatolites are organogenic, laminated, calcareous rock structures, the origin of which is clearly related to microscopic life, which in itself must not be fossilised.” Kalkowsky (1908) did not write this (see Riding, 1999, p. 323), but it has been repeated as if it were a literal translation from his paper (e.g., Ginsburg, 1991, p. 25; Feldmann and McKenzie, 1998, p. 201; Grotzinger and Knoll, 1999, p. 316; McLoughlin et al.,

2008, p. 96). Compounding this mistake, the somewhat awkward wording (use of “must not” rather than “need not”) has been cited as “paradoxical,” and “confusion” to be avoided, and also as an example of the deficiencies of genetic definitions (Grotzinger and Knoll, 1999, p. 316; McLoughlin et al., 2008, p. 96). In his 1908 paper, Ernst Kalkowsky did not provide a specific definition of stromatolite, but he did repeatedly emphasize that it is a laminated organic structure. He thought that the life forms involved were “*niedrig organisierte pflanzliche Organismen*” (simple plantlike organisms, Kalkowsky, 1908, p. 125). It is therefore reasonable to conclude that Kalkowsky essentially regarded stromatolites as laminated microbial deposits (Riding, 1999).

However, at the same time that support was growing for Kalkowsky’s (1908) biogenic interpretation of stromatolites, the contrary view was also being expressed. Reis (1908) interpreted stromatolites as inorganic precipitates, Bucher (1918) compared them with hot spring sinter. Semikhatov et al. (1979, p. 994) were also concerned by the similarities between microbial stromatolites and “morphologically similar structures of nonmicrobial origin” such as those in caves and hot springs, and therefore suggested their descriptive definition. Subsequent research has shown that some stromatolite-like deposits are essentially abiogenic (e.g., Grotzinger and Read, 1983; Grotzinger and James, 2000, p. 9). Pope et al. (2000, p. 1139) contrasted microbial and abiogenic stromatolites, and considered “isopachous stromatolites to have been dominated by chemogenic precipitation in the absence of microbial mats, and the growth of peloidal stromatolites to have been controlled by sedimentation in the presence of microbial mats.”

Fabric criteria can be used to distinguish abiogenic evenly layered sparry crust from fine-grained lithified microbial mats with uneven layering. In well-preserved examples, it should therefore be possible to tell abiogenic and biogenic stromatolites apart. However, as noted under microbialite, the millimetric interlayering of these two fabrics that can occur in hybrid stromatolites (Riding, 2008) makes such straightforward separation impossible. Consequently, stromatolites are regarded here, essentially, as laminated benthic microbial deposits, but they can contain abiogenic precipitates and be intimately inter-layered with them. In the marine realm, there is a strong secular perspective to this. Many Phanerozoic and Neoproterozoic stromatolites are probably essentially lithified microbial mats, whereas many older examples probably contain at least some precipitated abiogenic crust.

Microbialites, Stromatolites, and Thrombolites, Figure 2 Late Cambrian (late Franconian–early Trempealeauan) stromatolite (*Cryptozoon*), Hoyt Limestone, Petrified Gardens, Saratoga Springs, New York, USA. Coin diameter ~3 cm.

Stromatolite types

Stromatolite micro- and macrofabrics commonly intergrade with those of dendrolites and thrombolites (Figure 3). Their formation can involve up to three main processes: microbial precipitation, inorganic precipitation, and grain trapping (Figure 4). The main types represent

Microbialites, Stromatolites, and Thrombolites, Figure 3 Stromatolites and thrombolites based on micro/macrob fabric. All except wrinkled cohesive mats are syngedimentarily lithified by microbial and/or abiogenic processes. Fine-grained varieties include two distinctive types: (i) stromatolites with peloidal-microclotted microfabrics and (ii) dendrolites and thrombolites with abundant filamentous and other calcified microbial microfossils.

lithified microbial mat, sparry crust, and combinations of these (“hybrid stromatolite”).

Lithified microbial mat stromatolites exhibit a variety of intergradational fabrics. Two main types are fine-grained and coarse agglutinated. They form diverse stratiform, domical and columnar structures and, overall, tend to show relatively uneven to discontinuous layers with relatively poor inheritance and can include abundant fenestrae. Fine-grained stromatolites appear mainly to be products of syngedimentary microbial precipitation and are dominated by fine-grained (micrite, microspar) and filamentous fabrics. Fine-grained microfabrics are typically clotted and peloidal and are probably largely produced by heterotrophic bacterial calcification (e.g., dissimilatory sulfate reduction) of EPS and other cell products. Filamentous microfabrics are dominated by tubiform microfossils such as *Girvanella* that reflect photosynthetic cyanobacterial sheath calcification, but they too have fine-grained matrices. On their own, peloid-microclotted fabrics tend to be stromatolitic, and have been termed spongiostrome (Gürich, 1906; Pia, 1927, p. 36).

Filamentous fabrics tend to be more crudely layered and grade to thrombolitic. They have been termed porostromate (Pia, 1927, pp. 36–40), skeletal (Riding, 1977), and calcimicrobial (James and Gravestock, 1990). Coarse agglutinated stromatolites/thrombolites are produced by trapping sandy sediment by uncalcified EPS and erect filaments that can include microalgae. Present-day examples include some Shark Bay and Lee Stocking Island columns. They often have crudely layered macrofabrics (Logan, 1961) and have been termed thrombolitic stromatolites (Aitken, 1967).

Sparry crust (Riding, 2008) can form stromatolite-like abiogenic precipitates (Grotzinger and Rothman, 1996) characterized by even, often isopachous, laterally persistent layers with good inheritance (Pope et al., 2000). They have been most widely recognized in the Palaeoproterozoic and Mesoproterozoic (Grotzinger and Knoll, 1999, Fig. 6a, b), with microdigitate forms occupying peritidal environments (Grotzinger and Read, 1983) and isopachous laminite (Jackson, 1989) relatively deeper water facies.

it could resemble some *Conophyton* and *Baicalia* fabrics, as Bertrand-Sarfati (1976) suggested.

At the present day, intertidal and supratidal sediments are commonly colonized by cyanobacteria dominated mats in siliciclastic (e.g., Cameron et al., 1985; Stal et al., 1985), evaporitic (e.g., Gerdes et al., 2000), and carbonate (Black, 1933; Logan et al., 1974) environments (Figure 6). Where these mats are cohesive, but insufficiently early lithified, they do not show significant accretion but nonetheless stabilize layers of sediment. These microbialites that were unlithified during their formation can be preserved in place, and also imprinted and disrupted, e.g., by desiccation and water movement. They and their incorporated sediment may be cracked, curled, and folded, and this syndimentary deformation can be preserved after burial. Such patterned surfaces in

Microbialites, Stromatolites, and Thrombolites,

Microbialites, Stromatolites, and Thrombolites,
Figure 6 Wrinkled microbial mat with carbonate sediment; supratidal flat, Crane Key, Florida Bay, USA. Red pen cap ~5 cm long.

Mesoproterozoic limestones were named *Kinneyia* by Walcott (1914, p. 107, pl. 11, Fig. 3) and subsequently linked to “Runzelmarken” (wrinkle marks, Häntzschel and Reineck, 1968) and other mat-related structures (Hagadorn and Bottjer, 1997). They have also been termed microbially induced sedimentary structures (MISS) (Noffke et al., 1996). The exact origins of these bedding plane structures are probably complex and varied (Porada et al., 2008) but they have been widely linked to deformation of microbial mats and have been used to infer the presence of mats in the Proterozoic (Horodyski, 1982) and Archaean (Noffke et al., 2006).

Siliciclastic stromatolites

In contrast to wrinkle structures, siliciclastic stromatolites can possess large domical morphologies and considerable synoptic relief. They are much scarcer than carbonate stromatolites, and are only known from mixed siliciclastic-carbonate environments that provide both siliciclastic grains and the early lithification required to maintain their support (Martín et al., 1993). Most examples are Palaeozoic, e.g., Ordovician (Davis, 1968), Devonian (Draganits and Noffke, 2004), Carboniferous (Bertrand-Sarfati, 1994), and Permian (Harwood, 1990), but diverse examples also occur in the late Miocene of South-east Spain (Martín et al., 1993; Braga and Martín, 2000). Based on the proportion of siliciclastic grains they contained, Martín et al. (1993) recognized three compositional types: “carbonate,” <10%; “siliciclastic-carbonate,” 10–50%; and “sandstone,” >50%. They are typically metric, locally decametric, domes with both stromatolitic and thrombolitic macrofabrics, associated with marginal marine beach (Braga and Martín, 2000), fan-delta and conglomeratic debris-flow deposits (Martín et al., 1993), and also with oolitic stromatolites–thrombolites (Braga et al., 1995). Sediment within the more siliciclastic domes includes abundant quartz, mica, and lithic fragment sand, and occasional quartz and metamorphic rock granules and pebbles.

Thrombolites

Definition

Thrombolites (Greek: *thrombos*, clot; *lithos*, stone) are “cryptalgal structures related to stromatolites, but lacking lamination and characterized by a macroscopic clotted fabric” (Aitken, 1967, p. 1164).

Introduction

Aitken’s (1967) seemingly straightforward definition of thrombolite contained the seeds of more confusion than might have been anticipated. Since stromatolites are generally regarded as internally laminated; it could be expected that thrombolites are internally clotted. However, stromatolitic laminae are internal features of microbial carbonate, whereas “clot” could be used to describe both the external shape and internal structure of microbial carbonate (Figure 1). Aitken’s (1967) descriptions of Cambro-Ordovician examples, and his emphasis that thrombolite clotted fabric is macroscopic, have directed most researchers to regard “clots” as centimetric patches of microbial carbonate within interstitial sediment. In this view, a thrombolite dome consists of numerous such clots within lighter colored interstitial detrital matrix. Consequently, the dome has an overall macroclotted fabric, but the individual clots themselves are not necessarily internally composed of smaller clots, although they can be. This contrasts with stromatolitic domes in which each individual stromatolite is internally laminated and its shape is described separately, e.g., as domical, columnar, digitate, etc.

Aitken's (1967) concept of clots as patches of microbial carbonate within matrix is appropriate where they are irregularly rounded, but in digitate thrombolites the patches elongate into decimetric branches (e.g., Armella, 1994, Fig. 9) and use of "clot" to describe these is awkward. If some of Aitken's (1967) thrombolite domes contain dendritic fabrics, as seems likely, then why did he stress their clotted macrofabric? A likely explanation is that, in domes composed of radial branches, any section other than a vertical one through the dome center (e.g., Armella, 1994, Fig. 9) tends to show clot-like rounded outlines of oblique sections of branches. If this is correct, then to be consistent the branches should also be regarded as clots. This approach was followed by Armella (1994) and Kennard (1994) (although they used *thromboid* as an equivalent term to clot) to describe rounded lobate patches and elongate columns alike. There seems little doubt that this is what Aitken (1967) intended, and Shapiro (2000, p. 166) recognized that he used clot to describe the thrombolite columns themselves. Nonetheless, in describing similar branched Cambro-Ordovician thrombolites (*Favosamaceria*), Shapiro (2000) and Shapiro and Awramik (2006) broadened "clot" to refer to both millimetric clots within the branches and centimetric clots embedded in interstitial sediment. And there is a further complication. Aitken (1967) suggested that poorly laminated columns at Shark Bay are "thrombolitic stromatolites." As a result, in addition to describing Cambro-Ordovician domes with well-defined fine-grained clots, thrombolite has been applied to agglutinated present-day microbial columns in which the clots are much less distinct patchy fabrics.

These complications of usage still require clarification. At present, it is safe to say that "clot" (and the equivalent terms mesoclot and thromboid) has not been used consistently in thrombolite studies. It has been applied to millimetric patches within microbial carbonate, to centimetric lobate patches and also extended columns of microbial carbonate surrounded by detrital carbonate sediment, to transverse sections of these columns (here termed pseudoclots), and to diffuse patches of trapped sand, as well as to secondarily enhanced clots. Given these complications, it is understandable that earlier workers often referred to thrombolites as "unlaminated stromatolites" (e.g., Aitken, 1967, p. 1166; Pratt, 1982a; Schopf and Klein, 1992, p. 1202). Nonetheless, thrombolites can generally be regarded as benthic microbial carbonates with macroclotted fabric.

Thrombolite types

Two main types of thrombolite are calcified microbe and coarse agglutinated (Riding, 2000, pp. 192–193). Both intergrade with microbial mat stromatolites and primarily reflect the presence of major components that form irregular aggregates rather than thin layers. Nonetheless, the two types have quite distinct origins:

- (i) *Calcified microbe thrombolites* include the classic Cambro-Ordovician examples described by Aitken (1967) and also by Pratt and James (1982) and Kennard and James (1986). Aitken (1967) noted that burrows and trilobite fragments are common in these thrombolites, and examples of similar age often show mottled interiors and stromatolitic outer coatings (Figure 7). They consist of clots composed of framework whose most recognizable components are calcified microfossils, such as *Girvanella* filaments and *Renalcis* botryoids. The clots may be irregular centimetric amoeboid forms (Figure 8) or extend vertically into elongate (Armella, 1994, Fig. 9) meandriform and laterally amalgamated (Pratt and

James, 1982, Figs. 9, 12) branches named *Favosamaceria* by Shapiro and Awramik (2006), (Figure 1). The clots are surrounded by detrital sediment infill. Progression from irregular clots to elongate branches has confused descriptive terminology. Shapiro (2000) suggested that in branched forms the clots typical of thrombolites are to be found within the branches, although Aitken (1967) seems to have regarded the columns as clots. James and Gravestock (1990) used “calcimicrobe” (calcified microbial microfossil) to refer to filamentous and botryoidal fossils that are common in Cambrian reefs. These typically form dendrolite (Figure 9) and thrombolite (Figure 10) fabrics and include calcified cyanobacteria such as *Angusticellularia*, *Botomaella*, and *Girvanella*, and also *Epiphyton* and *Renalcis*, whose affinities are less certain. Calcified microbe thrombolites are widespread in shallow marine

environments during the Neoproterozoic and early Palaeozoic.

- (ii) *Coarse agglutinated thrombolites* are largely composed of fenestral microbially trapped sandy sediment within finer-grained microbially lithified matrix. They are closely associated with coarse agglutinated stromatolites (Figures 3 and 4) that Aitken (1967, p. 1171) described as “thrombolitic-stromatolites.” They are only known in the late Neogene and their development appears to be linked to the rise of algal-cyanobacterial mats able to trap coarse sediment.

Coarse-grained thrombolites in the late Miocene of South-east Spain are closely associated with stromatolite fabrics in composite domes and columns up to 1.5 m high and 4 m across (Martín et al., 1993; Braga et al., 1995; Feldmann and McKenzie, 1997). They include oolitic examples in which clotted fabric is produced by irregular fenestrae up to 15 mm in size (Riding et al., 1991a, p. 123). Braga et al. (1995, Fig. 8, pp. 358–359) attributed the formation of these thrombolite fabrics to “a complex of irregular agglutination, microbial calcification, skeletal encrustation, and erosional processes.”

Logan (1961) regarded Shark Bay columns as stromatolites but recognized that the lamination is often poor, describing some as “crudely laminated with laminae of 1–10 mm. in thickness” (p. 526, pl. 1, Fig. 4). Playford and Cockbain (1976, p. 403) observed that “Hamelin Pool stromatolites range from unlaminated (thrombolites) to finely laminated; most show only crudely developed lamination.” Walter (1972, p. 64) attributed “the crude lamination of many Shark Bay stromatolites” to the thick irregular mats and coarse sediment. Logan et al. (1974, p. 154) related carbonate fabric to mat type, with thick irregular pustular mat dominated by *Entophysalis* in particular producing “unlaminated to poorly laminated” fenestral fabric, and Gebelein (1974) suggested that clotted fabric could reflect degradation of organic material. Similar Bahamian subtidal columns (Dravis, 1983) are coarse-grained and crudely laminated (Dill et al., 1986) and it has been suggested that abundant algae, including diatoms in these mats contribute to the coarse texture and poor lamination typical of both Shark Bay (Awramik and Riding, 1988) and Bahamian (Riding et al., 1991b) columns.

Mesozoic-Cenozoic thrombolites: Thrombolites are also common in the mid-late Jurassic (e.g., Leinfelder et al., 1993; Parcell, 2002; Kopaska-Merkel, 2003; Mancini et al., 2004), often in association with sponges and stromatolites in deeper water (e.g., Jansa et al., 1988; Leinfelder et al., 1994, p. 37; Dromart et al., 1994) and with corals in shallow-water (e.g., Bertling and Insalaco, 1998; Dupraz and Strasser, 1999; Olivier et al., 2003; Olivier et al., 2006; Helm and Schülke, 1998, 2006). They exhibit a variety of forms, including

arborescent and pendant that commonly occur as thick crusts on frame-building invertebrates, and are also closely associated with a variety of problematic encrusting organisms such as *Bacinella*, *Lithocodium*, and *Shamovella/Tubiphytes*, as well as annelids and foraminifers (Leinfelder et al., 1993, Fig. 6; Olivier et al., 2003, Fig. 4). Similar – but more often stromatolitic – crusts occur in late Neogene, including present-day, scleractinian reefs (Riding et al., 1991c; Montaggioni and Camoin, 1993; Leinfelder et al., 1993, pp. 222–224), and provide important clues to the formation of microbial carbonate microfabrics (Reitner, 1993; Reitner et al., 2000). In addition, the macrofabrics of these Mesozoic-Cenozoic examples broadly resemble those of early Palaeozoic calcified microbe thrombolites, but with significantly different skeletal components. Their microfabrics are fine-grained, with peloids and microclotted micrite (Olivier et al., 2006, Fig. 9), similar to those of many lithified microbial mat stromatolites.

Tufa thrombolite and stromatolite (Riding, 2000, pp. 191, 194) forms in calcifying lakes and streams as a result of cyanobacterial calcification that includes sheath impregnation and encrustation, together with calcification of associated microbes. It was comparisons with freshwater tufa that first led to recognition of links between stromatolites and cyanobacteria (Walcott, 1914; Roddy, 1915). These complex fabrics show considerable variety due to local differences in organisms and the extent of biocalcification and external encrustation. There are similarities between tufa stromatolites and hybrid crust stromatolites (Riding, 2008, p. 88) (Figure 4).

Kennard and James (1986, p. 498) noted that, although “poorly laminated and partially clotted microbial structures” occur on some present-day hypersaline marine shorelines (Laguna Mormona, Shark Bay) and in some lakes of various salinities (Great Salt Lake, Lake Clifton, Green Lake), in these examples “individual microbial clots are generally poorly defined” and “form an irregular, botryoidal-like, mesoscopic fabric that is unlike any of the fabrics observed by us in Lower Paleozoic thrombolites.” However, Moore and Burne (1994, pp. 23) considered that thrombolites in brackish to normal marine Lake Clifton, Western Australia, do closely resemble some early Palaeozoic examples in mesoclot shape and “the interframework of infilled fenestrae” and they pointed out that in Lake Clifton filamentous cyanobacteria (*Scytonema*) are important in thrombolite formation. Moore and Burne (1994, p. 21) noted that fine laminae, initially present in the Lake Clifton structures, are syndimentarily destroyed during mesoclot formation as carbonate precipitation continues, and also that the interframework fenestrae are intrinsic features “primarily related to the topography of the surface of the developing microbialite rather than to excavation of the structure by metazoan activity.” Great Salt Lake “algal mounds,” that consist of precipitated aragonitic framework and internal sediment (Halley, 1976, p. 439, Fig. 3), have a sub-centimetric thrombolitic fabric. Ferris et al. (1997)

suggested that thrombolitic fabrics in Kelly Lake, British Columbia, reflect a greater degree of calcification than in stromatolites.

Post-depositional thrombolites Aitken (1967, p. 1171) noted that thrombolite macroclots are prone to accentuation by recrystallization. This emphasizes a fundamental difference from stromatolites, whose laminae are essentially primary and not likely to be significantly enhanced by diagenesis. In contrast, clots could be significantly enhanced, e.g., by selective dolomitization, and in some cases secondarily produced, e.g., by bioturbation.

Stromatolites and thrombolites through time

Microbialite types are generally long ranging. Nonetheless, they show some distinctive differences in time distribution (Figure 11). Marine sparry crusts and hybrid stromatolites are typically Precambrian, and fine-grained stromatolites and thrombolites mainly range Neoproterozoic to the present day. Wrinkle structures show the longest range, whereas lithified coarse-grained carbonate thrombolites and stromatolites are only known from the past 10 Ma or less.

Archaean and Proterozoic

Stromatolites are relatively scarce in Archaean rocks until nearly the end of the eon. Their history begins with ~3.45 Ga coniform examples in the Pilbara region of Western Australia. These show fine continuous laminae (Lowe, 1980, 1983) and sparry microfabrics (Hofmann et al., 1999, Fig. 3). Their origins, and those of other Pilbara stromatolites, have been debated (e.g., Lowe, 1994, 1995; Buick et al., 1995), with recent studies supporting a biogenic origin (Hofmann et al., 1999, p. 1260–1261; Allwood et al., 2006, p. 717). Wrinkle and associated structures also suggest the presence of microbial mats in ~2,900 Ma siliclastic sediments of South Africa (Noffke et al., 2008), but these too are generally scarce. However, stromatolites are abundant in the ~2.55 Ga Campbellrand-Malmani carbonate platform of South Africa, locally forming elongate domes 10 m across and 40 m or more in length (Beukes, 1987, p. 9). In addition, these late Archaean carbonates contain distinctive “fenestrate microbialites” (Sumner and Grotzinger, 2004) consisting of millimetric to centimetric areas of light colored cement outlined by thin net-like layers (Figure 12). These have been interpreted as wispy convoluted microbial mats that were encrusted by calcite as they formed (Sumner, 1997a, b).

Large, often decametric, stromatolites are also conspicuous components of Proterozoic carbonate platforms (e.g., Grotzinger, 1986, p. 833; Petrov and Semikhatov, 2001, Fig. 6, p. 269). Where they are well preserved, they often show interlamination of sparry and micritic layers (e.g., Sami and James, 1996, p. 217). These dark-light layers that appear to represent alternations of lithified mat and abiogenic crust, are typical of “hybrid stromatolites” and are well seen in some *Conophyton* and *Baicalia* (Riding,

Microbialites, Stromatolites, and Thrombolites, Figure 11 Approximate time distributions of major categories of marine microbialites. Coarse agglutinated mats are mainly Neogene. Fine-grained mats and thrombolites are mainly Neoproterozoic and Phanerozoic. Marine “sparry” and “hybrid” crusts are mainly Archaean and Proterozoic. Wrinkle structures range Archaean to present-day. For some possible controls, see [Figure 14](#).

2008). Such incorporation of thin abiogenic sparry crusts appears to have contributed significantly to the size and relief of stromatolites throughout the Palaeo- and Mesoproterozoic. During the same period, extensive sheets of very small “microdigitate” stromatolites, typically <5 mm wide and <20 mm high (Hoffman, 1975, p. 262) were common in shallow peritidal environments ([Figure 13](#)). These “tufas” have been interpreted as essentially abiogenic (Grotzinger and Read, 1983).

An important control on Archaean-Proterozoic stromatolite formation was gradual decline in seawater carbonate saturation state (Grotzinger, 1989b; Grotzinger and Kasting, 1993). This progressively reduced stromatolite abundance (Grotzinger, 1990) and mediated a long-term trend from sparry crust to micritic carbonate sediments (Grotzinger and Kasting, 1993; Kah and Knoll, 1996). Transition to carbonate mud-dominated platforms ~1,400–1,300 Ma ago (Sherman et al., 2000) preceded the appearance of sheath-calcified cyanobacteria ~1,200 Ma ago (Kah and Riding, 2007). This significant transition, which led to Neoproterozoic development of calcimicrobial thrombolites (Aitken and Narbonne, 1989; Turner et al., 1993, 2000a, b), could reflect induction of CO₂-concentrating mechanisms (CCM) in cyanobacteria in response to fall in CO₂ levels below a threshold near ten times present-day levels (Riding, 2006) ([Figure 14](#)). CCMs are responses to reduced availability of inorganic carbon for photosynthesis, and in cyanobacteria include active bicarbonate uptake that

locally increases sheath pH, promoting calcification (Merz, 1992). Calcified filaments, such as *Girvanella*, altered microbial carbonate fabrics, disrupting stromatolite layering and promoting thrombolitic macro-clotted fabric. In subtidal environments, Neoproterozoic stromatolites are commonly interlayered with thrombolites with filamentous, clotted, and spongy “cellular” fabrics (Aitken and Narbonne, 1989) comparable with those of Cambro-Ordovician thrombolitic bioherms (Turner et al., 1993; 1997, p. 441, 449; 2000a, [Figs. 6e, 8h](#) and i).

Stromatolite decline

Stromatolites show long-term decline in abundance that may have commenced as early as the Palaeoproterozoic (Grotzinger, 1990) and is still observed in the Phanerozoic. Fischer (1965) suggested that decline since the Ordovician could reflect both reduction in carbonate saturation and competition by eukaryotes. Competition was subsequently emphasized when it appeared that marked late Proterozoic fall in stromatolite morphotypic diversity coincided with metazoan evolution (Awramik, 1971), but inception of decline prior to the appearance of metazoans implicates reduction in saturation state as the major influence (Grotzinger, 1990). It was also suggested that Cambrian thrombolites reflected disruption of stromatolites by burrowing organisms (Walter and Heys, 1985, pp. 150–151). However, Cambrian-Ordovician thrombolite fabrics are dominated by calcimicrobes that resist disruption (Kennard and James, 1986, p. 494) and

Microbialites, Stromatolites, and Thrombolites,

it has since been recognized that thrombolites appeared in the Neoproterozoic (Aitken and Narbonne, 1989), and possibly ~ 1.9 Ga in the Palaeoproterozoic (Kah and Grotzinger, 1992).

This leaves the question of the significance of trends in stromatolite diversity. Stromatolite shape reflects original

synoptic relief, determined by accretion rate relative to adjacent sediment (Figure 15). Low relative accretion rate results in low relief that makes stromatolites more prone to lateral incursion by sediment, thereby fostering complex shapes such as digitate forms (Figure 16). In contrast, high relative accretion rate results in high relief and simple shapes, such as domes and cones. Consequently, although mid-Proterozoic increase in morphotypic diversity, e.g., in branched stromatolites, has been regarded as a proxy for abundance, it more likely reflects low synoptic relief due to reduced relative accretion rate. Paradoxically, therefore, increased diversity could be sign that stromatolite growth was in decline due to reduced microbial growth and/or reduction in syndimentary lithification.

Snowball Earth

The prolonged warm Mesoproterozoic interval (Jenkins, 2003) was followed by Neoproterozoic (Sturtian, ~ 0.7 Ga Ma, Walter et al., 2000; Marinoan, ~ 0.635 Ga, Bodiselitsch et al., 2005) glaciations. Lower temperature and $p\text{CO}_2$ levels would have decreased seawater saturation state, hindering microbial calcification generally. Cooling would also have favored diffusive entry of CO_2 into cells and therefore may have slowed CCM development, further reducing cyanobacterial calcification. Nonetheless, microbialites are locally conspicuous in Cap Carbonates that immediately follow glacial deposits (e.g., Hoffman and Schrag, 2002; Corsetti and Grotzinger, 2005). Cap Carbonates have been suggested to reflect precipitation from seawater highly saturated for carbonate minerals as a result of alkaline upwelling and enhanced terrestrial weathering (Grotzinger and Knoll, 1995; Hoffman and Schrag, 2002). In the ~ 600 – 700 Ma Noonday Dolomite of California, narrow laterally amalgamated stromatolites define tubes of intervening detrital sediment fill (Figure 17). The overall organization of some Cambro-Ordovician *Favosamaceria* thrombolites (Shapiro and Awramik, 2006) resembles these “tubestones” (Corsetti and Grotzinger, 2005, p. 360).

Following Neoproterozoic “snowball” glaciations, global warming and O_2 rise could have reactivated CCM development, and rising temperature, calcium (Brennan et al., 2004), and $p\text{CO}_2$ (Bernier and Kothavala, 2001) levels would have increased seawater saturation state, stimulating microbial calcification (Riding, 2006). This favored microbialite resurgence, and dendrolites, thrombolites, and stromatolites all became widespread in the early Cambrian (Rowland and Shapiro, 2002) (Figure 18).

Phanerozoic

Secular distribution

Both reefal microbial carbonates (Kiessling, 2002, Fig. 16) and calcified cyanobacteria (Arp et al., 2001) decline in abundance during the Phanerozoic, but this trend shows marked fluctuations. They are common in the late Cambrian-early Ordovician and late Devonian-early Mississippian, and scarce during the Cenozoic.

Microbialites, Stromatolites, and Thrombolites, Figure 14 Some secular trends and possible controls on microbial carbonate developments. Proterozoic stromatolite abundance (Grotzinger, 1990) and morphotypic diversity (Awramik and Sprinkle, 1999), together with Phanerozoic reefal microbial carbonate abundance (Kiessling, 2002). These suggest overall long-term decline for at least the past 1,000 Ma. Reduction in both Sparry Crust and Hybrid stromatolites ~1,000 Ma ago may reflect decline in seawater carbonate saturation (Grotzinger, 1990). Stromatolite-like sparry crust occurs sporadically in the Phanerozoic, particularly in evaporite basins (Pope et al., 2000). Increase in thrombolites ~1,200–1,000 Ma ago could reflect development of cyanobacterial sheath calcification, reflecting inception of CO₂-concentrating mechanisms (CCMs) as CO₂ levels declined to ~10 times present atmospheric level (PAL) (Riding, 2006). Inferred Proterozoic CO₂ trend based on Sheldon (2006), Kah and Riding (2007), Hyde et al. (2000) and Ridgwell et al. (2003). Phanerozoic CO₂ trend from Berner and Kothavala (2001, Fig. 13). Threshold for CCMs (10 times PAL CO₂) based on Badger et al. (2002). Late Neogene inception of Coarse agglutinated stromatolites and thrombolite could in part reflect incorporation of diatoms into microbial mats and also generally low values of seawater carbonate saturation.

Fischer (1965) suggested that eukaryote competition and reduction in carbonate saturation state contributed to stromatolite decline from the Ordovician onward.

Carbonate saturation: Comparison with seawater saturation state for CaCO₃ minerals calculated from modeled seawater and CO₂ values shows broad positive correspondence with peaks of microbial/cyanobacterial carbonate abundance during much of the Palaeozoic and Mesozoic (Riding and Liang, 2005), supporting Fischer (1965). Lack of correspondence during the interval ~120–80 Ma ago (when calculated saturation ratio is high but microbial carbonate abundance was low) could reflect removal of carbonate deposition by pelagic plankton that significantly reduced actual saturation state.

Competition: The role of metazoan competition in late Proterozoic and early Palaeozoic stromatolite history is uncertain, and it is debatable whether metazoan grazing significantly affected stromatolite development (Pratt, 1982b) so long as carbonate saturation was high enough to ensure extensive early lithification of microbial mats. Nonetheless, it seems likely that from at least the mid-Ordovician onwards, overgrowth by skeletonized algae and invertebrates inhibited the formation of domical stromatolites and thrombolites. Subsumed within complex reef structures, microbial carbonates would instead have formed patchy and irregular crusts on and around skeletal organisms. Nonetheless, they were often important reef components (Kiessling, 2002, Fig. 16).

Microbialites, Stromatolites, and Thrombolites,

Figure 15 Hypothetical interpretation of the significance of stromatolite shape. Shape is determined by synoptic relief that in turn reflects accretion rate of the stromatolite surface relative to adjacent sediment. In this view, enhanced stromatolite accretion generates high relief and simple shapes, such as columns, cones, and domes. In contrast, relatively low stromatolite accretion results in low relief. As a result, the stromatolite surface is prone to overlap by adjacent sediment, generating branching and irregular margins.

Microbialites, Stromatolites, and Thrombolites,

Figure 16 *Gymnosolen*, digitate stromatolite, Dalien, China, ~1.0 Ga.

Disaster biotas: The concept of stromatolite decline resulting from algal-metazoan diversification (Fischer, 1965; Garrett, 1970; Awramik, 1971) has also given rise to that of stromatolite resurgence in the aftermaths of mass extinctions (Schubert and Bottjer, 1992, p. 885). In this view, if metazoans can competitively exclude microbial carbonates then temporary reduction in metazoan abundance and diversity in the immediate aftermaths of mass

Microbialites, Stromatolites, and Thrombolites,

Figure 17 Laterally amalgamated columnar stromatolites (light color) separated by slightly darker tubular fills of detrital sediment. Noonday Dolomite, late Neoproterozoic, Mesquite Mountains, California, USA.

extinctions should permit temporary increase in microbial carbonates. Schubert and Bottjer (1992, 1995) interpreted early Triassic stromatolites as “post-mass extinction disaster forms.” However, whereas microbial carbonate reefal abundance also increased noticeably in the aftermath of late Devonian extinction, it did not increase following end-Ordovician, end-Triassic, and end-Cretaceous mass extinctions (Riding, 2006). Nonetheless, it is likely that in these situations, unconstrained by algal and invertebrate reef organisms, microbial mats were able to develop distinctive morphologies, and large domes, columns, and digitate structures have been reported, e.g., at the Permian-Triassic boundary in Sichuan, China (Kershaw et al., 1999).

Thrombolites: Flügel (2004, p. 378) suggested that thrombolite abundance also declined after the Cambrian, although they were still locally conspicuous, e.g., in the Silurian (Kahle, 2001), Devonian (Shapiro, 2000, p. 166), Mississippian (Webb, 1987, 2005), and near the Permian-Triassic transition (Kershaw et al., 1999; Ezaki et al., 2008). Thrombolites have been widely reported in the mid-late Jurassic (see Mesozoic-Cenozoic thrombolites, above), broadly coincident with the last major peak of abundance of calcified marine cyanobacteria (Arp et al., 2001, Fig. 3d).

Evaporite stromatolites: In addition to metazoan extinction, localized increase in carbonate saturation in evaporite basins will favor microbialite development. Pope et al. (2000, p. 1139) noted that isopachously laminated stromatolites, which they considered to be dominantly abiogenic, are well developed in association with major evaporite successions and cited examples in the Proterozoic and Phanerozoic, including the Silurian Michigan Basin of North America and the late Permian Zechstein Basin of northern Europe (Pope et al., 2000,

Figs. 7, 9). These conditions therefore marked temporary returns to conditions that promoted formation of the sparry and hybrid crusts typical of the Archaean and early Proterozoic.

Neogene coarse-grained thrombolitic stromatolites

Well-known present-day examples of columns and domes occur in wave- and current-swept environments at Shark Bay (Logan, 1961) and the Bahamas (Dravis, 1983; Dill

Microbialites, Stromatolites, and Thrombolites, Figure 18 Late Cambrian (Trempealeauan) thrombolite overlain by stromatolite, Smoky Member, Nopah Fm, Dry Mountain, California, north-western Death Valley National Park, USA. Pen ~15 cm long.

et al., 1986; Riding et al., 1991b; Reid et al., 2000). They accrete bioclastic and ooid sand, and have crudely layered (Logan, 1961) and thrombolitic (Aitken, 1967, p. 1171) fabrics. Several factors conspire in their formation: water movement, mat community, and seawater chemistry. High-energy grainy conditions facilitate trapping by lifting sand to the accreting mat surface, and simultaneously deter overgrowth by reefal encrusters (Dill et al., 1989, p. 10). At Shark Bay, seasonal hypersalinity also limits competitors. Together with rapid accretion this allows decimetric, and locally metric, columns to develop. Accretion is high because the mats are thick and soft, with abundant EPS (Decho et al., 2005). In addition to cyanobacteria, they contain diatoms and filamentous green algae that enhance trapping ability (Awramik and Riding, 1988; Riding et al., 1991b). The upper mat remains soft and sticky because it is largely uncalcified, and the early lithification necessary to support these large columns mainly occurs in, or below, the lower part of the mat. Microbial lithification by sulfate reduction (Visscher et al., 2000) is limited to very thin micritic crusts (Reid et al., 2000), cyanobacterial sheaths are uncalcified (Reid et al., 2000, p. 992), and calcification of algal filaments mainly occurs in cavities (Dravis, 1983; Whittle et al., 1993, p. 224). Formation of these coarse-grained thrombolitic stromatolites is therefore largely due to their thick, soft, EPS-rich mats. These in turn reflect a combination of Cenozoic circumstances: (i) seawater saturation state that is too low for cyanobacterial sheath impregnation, but permits early lithification and (ii) the presence of fast-growing microalgae, such as diatoms, which – from a geological standpoint – are relative newcomers to mat communities (Figure 14). Coarse-grained thrombolitic stromatolite domes and columns are well developed in the late Miocene of South-east Spain (Riding et al., 1991a; Braga et al., 1995; Feldmann and McKenzie, 1997) (Figure 19) but are not known in older rocks.

Microbialites, Stromatolites, and Thrombolites, Figure 19 Coarse-grained, oolitic, composite leiolite-stromatolite-thrombolite domes, late Miocene (Messinian), Joyazo, Almería, South-east Spain. Red pen, lower left, ~15 cm long.

Summary

During the Archaean and much of the Proterozoic, both microbial mat growth and abiogenic precipitation were involved in stromatolite development that, locally, was particularly abundant from the latest Archaean to early Neoproterozoic (Grotzinger and Knoll, 1999). The combination of these biogenic and abiogenic factors was responsible for the rapid growth that enabled stromatolites, ranging from extensive small microdigitate sheets (Grotzinger and Read, 1983) to decametric domes (e.g., Hofmann, 1998, pl. 8a), to dominate carbonate platforms for 1,500 million years. Well-preserved stromatolites with dark-light lamination (Sami and James, 1996; Petrov and Semikhov, 2001) suggest that lithified mat growth alternated with abiogenic sparry crust precipitation on a millimetric scale to form inter-layered hybrid crust stromatolites (Riding, 2008).

Decline in sparry crusts and hybrid stromatolites ~1,000 Ma ago probably largely reflects reduction in seawater saturation (Grotzinger, 1990). This change also broadly coincided with the inception of cyanobacterial sheath-calcification in the Mesoproterozoic. This important development may reflect induction of CO₂-concentrating mechanisms (CCM) to assist photosynthetic carbon uptake as CO₂ levels declined (Riding, 2006). It transformed microbialite fabrics, and calcified microbe thrombolites and stromatolites with filamentous fabrics were conspicuous in shallow subtidal environments until the early Ordovician. Subsequently, stromatolites and thrombolites were widely subsumed within algal-invertebrate reefs. In these closely packed habitats, they lacked space to develop classic dome and column morphologies, and instead mainly formed reefal crusts and irregular masses. Only where competitors were environmentally excluded, or absent (as in mass extinction aftermaths), did microbial domes briefly develop extensively.

Both competition and declining carbonate saturation limited the abundance of marine microbialites from the Ordovician onwards (Fischer, 1965), and they are much less widespread and abundant in the Cenozoic than in the Palaeozoic. But microbialite communities have the ability to reinvent themselves. Diatoms together with other microalgae have significantly enhanced mat trapping ability. In environments where reefal overgrowth is limited, and coarse grains abundant, these soft mats can create large coarse-grained columns, as at Shark Bay and Lee Stocking Island. Internally these have distinctive crudely layered thrombolitic stromatolite fabrics (Aitken, 1967); in external shape, they closely resemble some Palaeoproterozoic stromatolites.

Microbialites have changed significantly during their extraordinarily long history in shape, size, fabrics, and abundance. They have responded to microbial evolution, to environmental changes that have affected both carbonate sedimentation and microbial metabolism, and to the evolution of other organisms. To add to this complexity, whereas stromatolites are essentially lithified microbial mats, they may be intimately associated with abiogenic crusts.

Microbialites archive important geobiological changes in atmospheric composition, seawater chemistry, mat evolution, and biotic interaction. Their study continues to offer many challenges and opportunities.

MICROBIAL-METAL BINDING

Kurt O. Konhauser, David A. Fowle
 University of Alberta, Edmonton, Alberta, Canada

Definition

The accumulation of metal cations to microbes, largely through adsorptive processes to the outer cellular surfaces.

Overview

All bacteria have low isoelectric points (below pH 2 in most cases), and consequently, they interact with soluble metal cations and have them intimately associated with their surfaces (Harden and Harris, 1953). Considering their ubiquity in the near-surface environment and their characteristically large surface area-to-volume ratios, bacteria can have a significant influence on metal mobility and speciation in these settings.

Some bound metals (e.g., Ca and Mg) serve the purpose of stabilizing the negative charges of the anionic functional groups, and thus are relatively “fixed” into place, while other metals are much more exchangeable and provide a temporary positive charge to counter the negative charge induced by the deprotonation of the cell’s surface functional groups (Carstensen and Marquis, 1968). The strength of the metal–microbial bond is quantified by the surface complexation/binding constant (K_M), where M refers to the specific metal of interest. The greater its surface complex formation constant, the less likely

a metal cation will be desorbed into solution. Metal cation sorption is also directly affected by pH, which dictates metal partitioning (or speciation) between solid and soluble phases, and hence, controls its mobility, reactivity, and toxicity in aquatic environments. Of particular importance here is the hydrolysis constant, which measures the tendency of proton release from the hydration sphere of the cation. Figure 1 depicts a generalized adsorption edge curve for a metal binding to a bacterial surface. As pH increases, the cell wall deprotonates and adsorption of the positively charged metal cation increases, but in some instances, adsorption may actually decrease at high pH values as metal hydrolysis is enhanced.

Much of our understanding about how bacteria bind metals stems from the pioneering work of Terry Beveridge on metal accumulation by the Gram-positive bacterium, *Bacillus subtilis* (Beveridge and Murray, 1976). His research demonstrated that it was the carboxyl groups within the peptidoglycan that were the most electronegative sites, and that the bulk of the binding capacity was associated with the cell wall. In similar studies with Gram-negative cells, such as *Escherichia coli*, it was demonstrated that they did not bind as much metal from solution as did their Gram-positive counterparts, a pattern stemming simply from the smaller amounts of peptidoglycan associated with the *E. coli* cell walls (Beveridge and Koval, 1981). Many Gram-positive and Gram-negative bacteria also produce extracellular polymers (EPS), and due to their hydrated nature, dissolved metals can freely diffuse throughout the structure, binding to the anionic carboxyl groups of uronic acids and the neutrally charged hydroxy groups of sugars (Geesey and Jang, 1989). By possessing a large and reactive surface area, it is thus not

unexpected that a number of studies have also documented that encapsulated bacteria bind more metals than nonencapsulated varieties (Rudd et al., 1983). Indeed, species producing EPS can tolerate higher metal concentrations than those that do not, and it has been shown that the proportion of encapsulated bacteria increases in metal-polluted sediment, whereas mutants that cannot produce capsules die off (Aislabie and Loutit, 1986).

Irrespective of the bacteria studied, what was repeatedly observed was that considerable variations in metal immobilization could be displayed by a single species. In some instances, cell walls were diffusely stained (Figure 2), while at other times so much metal was fixed to the cell surface that it formed a distinct mineral phase (Figure 3). This led Beveridge and Murray (1976) to originally propose a two-step mechanism for the metal adsorption process; the first step in time is an electrostatic interaction between the metal cations and the anionic sites in the cell wall/EPS. This interaction then acts as a nucleation site for the deposition of more metal cations (and anions) from solution, potentially leading to biomineralization. The size of the deposit depends on a number of variables, including the concentration of ions and the amount of time through which the reactions proceed. If sufficient time exists, then the mineral product grows in size within the intermolecular spaces until it is physically constrained by the organic polymers. The end result is a bacterial wall/EPS that contains copious amounts of metal, often approaching the mass of the bacterial cell itself (Beveridge, 1984).

Microbial-Metal Binding, Figure 1 Generic adsorption curve for a metal cation binding to a bacterial surface. Metal adsorption increases as pH increases and cell wall functional groups deprotonate.

Microbial-Metal Binding, Figure 2 Transmission electron micrograph (TEM) of the lab-cultured cyanobacterium *Anabena* sp. that was stained with uranium acetate and lead citrate to reveal cell ultrastructure. Note the dark staining of the cell wall and some of the cytoplasmic constituents.

Microbial-Metal Binding, Figure 3 TEM image of two unidentified bacteria surrounded by iron-stained extracellular polymers. The dark grains at the top right are ferric hydroxide, $\text{Fe}(\text{OH})_3$. These cells grew naturally in Fe-rich hydrothermal fluids at the Lysuholl hot spring in Iceland. From Konhauser (2007).

Although binding of cations to a microbial surface is largely an electrostatic phenomenon, the structural and compositional complexity of the wall or EPS, as well as the unique physicochemical properties of each element, adds a level of complexity to the overall process. In other words, protons and each different cation should be capable of interacting in a distinctive way with surface ligands, such that a cell's surface will display varying affinities for binding different cations. Moreover, in natural systems, a multitude of cations (and anions) exist that should compete with one another for complex formation. This realization has led to a number of metal binding studies that have compared the relative affinities of protons and various cations for the anionic ligands on the cell surfaces of different microorganisms, by techniques that involve displacing one by another. Those studies have highlighted two very important points, the first being that metals and protons compete for the same surface sites, and as solution pH decreases, the functional groups become protonated, displacing loosely bound metal cations (Fowle and Fein, 2000). The second finding is that microbial-metal interactions are largely abiotic, nonspecific, and reliant upon thermodynamics (Warren and Haack, 2001). Some of the most important factors that influence metal binding to cells are (1) the ionic potential of the solution, (2) cell wall/EPS ligand spacing and their stereochemistry, (3) the ligand composition, and (4) the balance between the initial electrostatic attractions between a soluble metal cation and the organic ligands, and the subsequent covalent forces that arise from electron sharing across a metal cation-ligand molecular orbital (Williams, 1981). These properties are largely understood, and given

sufficient information about the environment in which a microorganism is growing, it is possible to extrapolate and predict metal binding patterns on a cell surface.

In the past decade, metal binding experiments have begun to emphasize the stability constants for metal-organic ligand interactions and elucidate how metal binding correlates with cell surface reactivity during changes in solution chemistry. Moreover, unlike many of the early biosorption studies that were carried out in supersaturated conditions with respect to the metal of interest, more recent studies have focused on describing metal-microbe interactions at more realistic undersaturated conditions. The goal for much of this research is to develop geochemical speciation models that describe how microorganisms interact with metals and mineral surfaces under varying geochemical conditions, thus enabling their use in reactive transport models (Fein, 2000 for review). The reactions can be quantified using two different approaches: (1) bulk partitioning relationships or (2) surface complexation models (SCM). In the first instance, partitioning models, such as K_d , Freundlich and Langmuir isotherms, can easily be applied to complex systems because they do not require a detailed understanding of the nature of the surfaces or the adsorption/desorption mechanisms involved. However, they are system-specific, meaning that the results from a set of experiments can be inapplicable to different systems. In contrast, the SCM takes into account the effects of changing pH, solution composition and ionic strength, the acid-base properties of surface functional groups, competitive sorption with other solutes, and solid-phase reactivity and mineralogy. It then draws upon that information to extrapolate to conditions beyond those tested in the laboratory. However, in order to utilize these models in more complex settings, more detailed understanding is required of not only surface and aqueous speciation but also the adsorption and desorption mechanisms.

New experimental techniques are helping to elucidate both the mechanisms and stoichiometry of metal-microbe interactions. Spectroscopic data provide more direct evidence of the metal coordination environment than traditional SCM and partitioning models. For example, metal binding onto *B. subtilis* has been examined by X-ray absorption spectroscopy (XAS) and provided estimates of metal:functional group stoichiometry (Boyanov et al., 2003; Kelly et al., 2002). Mechanisms of metal binding have been directly probed via time-resolved laser-induced fluorescence spectroscopy (TRLFS) and have shown that some metals preferentially bond to one functionality in the cell wall (Panak et al., 2000), while others are less specific (Texier et al., 2000; Markai et al., 2003). A notable recent advance in constraining the thermodynamics of metal-microbe adsorption reactions was the combination of calorimetric data with SCM to generate site-specific enthalpies and entropies of metal adsorption onto the cell wall of *B. subtilis*. This work indicated that heavy metals bind to the cell wall via inner sphere complexation (e.g., no interlayer water molecules) with multiple anionic

oxygen ligands. Stoichiometry and temperature dependence of the metal–bacteria adsorption reactions can also be extracted using this approach (Gorman-Lewis et al., 2006).

Summary

Microbial–metal adsorption includes the electrostatic and chemical association of metals with the organic functional groups of microbial cell surfaces. This can be considered a passive process driven by the electronegativity of the microbial cell wall/EPS and the Gibbs free energy of the adsorption reactions. These adsorption reactions seem to be dominated by binding of cations to the oxygen containing moieties on the cell surface. Future advances in elucidating the mechanisms of metal adsorption to microbes will come from combining novel analytical techniques, such as colorimetry and spectroscopy, with bulk partitioning studies and site-specific adsorption models.

Definition

Destruction of rocks and minerals by biological activities has been termed bioerosion (Neumann, 1966). It includes mechanical as well as chemical effects, that is, bioabrasion and biocorrosion (Schneider, 1976; Golubic and Schneider, 1979). However, both the processes often co-occur; they are functionally interconnected and mutually supportive. Biocorrosion can result from the activity of macro- or microorganisms and, thus, is called macrobiocorrosion and microbiocorrosion. Microbiocorrosion can also be closely associated with microbial rock formation and consolidation in stromatolitic structures (Reid et al., 2000; Macintyre et al., 2000; Garcia-Pichel et al., 2004; Dupraz and Visscher, 2005). In fact, the oldest known fossils of microboring organisms were located in lithified horizons of silicified stromatolites (Zhang and Golubic, 1987).

Definition

Microsensors are needle-shaped sensors ([Figure 1](#)) that can be inserted in biologically active matrices, such as sediments, to measure directly concentrations of certain compounds.

Introduction

In sediments, microbial mats, and biofilms steep gradients of substrates and products develop, due to high metabolic activities and mass transfer limitations (see Chapters [Biofilms](#); [Microbial Mats](#); [Sediment Diagenesis – Biologically Controlled](#)). Stratifications of microenvironments develop that determine the existence and activity of microbial consortia. For example, in active biofilms oxygen can penetrate less than 50 μm (de Beer et al., 1994c; de Beer et al., 1993), in sediments oxygen penetrates typically less than 2 mm (de Beer, 2001; Jørgensen and Revsbech, 1985; Meyers et al., 1987; Revsbech,

Microsensors for Sediments, Microbial Mats, and Biofilms, Figure 1 Left panel, microsensors for oxygen (left sensor), for pH (middle), and for H_2S (right sensor). The right panel zooms further in on the tip of an oxygen sensor, showing the gold-plated electrode behind a silicon membrane, the ticks on the ruler are 1 μm .

1983; Sorensen et al., 1981; Sweerts and de Beer, 1989). Below the oxic zone anaerobic microbial processes can occur, such as denitrification and sulfate reduction (see Chapter [Sulfur Cycle](#)), that determine the element cycling (the coupled degradative and chemolithotrophic processes) in the system as a whole. Stratifications on such a small scale cannot be studied by more classical techniques such as pore-water extraction and chemical analyses. Extraction is impossible on such small scales, as it is highly destructive for the system and concentrations will have changed during the extraction procedure. To study such stratified systems we need microsensors that are minimally invasive and directly measure the concentrations without disturbing the system in which we measure. Moreover, as the system is not disturbed by microsensor analyses, we can perform sequences of measurements and, for example, study how the system responds to environmental changes. Microsensor measurements have enormously enhanced the insight in the vertical distribution of microbial processes in sediments. Microsensors were originally developed for physiological studies in animal and plant tissues, and even for intracellular measurements (Ammann, 1986; Hinke, 1969; Thomas, 1978), but soon applied in environmental studies (Bungay et al., 1969). They became an established technique for ecological studies by the developing work of Revsbech, who made them more robust and invented a large diversity of sensors (Kühl and Revsbech, 2000; Revsbech and Jørgensen, 1986).

Principle

The microsensors most commonly used for environmental studies are of the electrochemical principle, i.e., the compound to be measured induces a current (amperometric) or a potential (potentiometric) proportional to the concentration of the solute. The sensors are commonly made of glass, as this is easy to pull to fine tips, is inert and has excellent isolation properties. It involves the pulling of micropipettes in flames and electrical coils to exactly the desired geometry, thickness, and tip opening, followed by inserting the actual electrodes into these capillaries (Figure 1). The electrodes are mostly platinum wires, etched to micron thickness, and coated with a thin insulating glass layer. The making of microsensors is a fine art. For detailed descriptions of sensor preparation and electrochemical principles the reader is referred to various manuals and reviews (Gieseke and de Beer, 2004; Kühl and Revsbech, 2000; Revsbech and Jørgensen, 1986; Thomas, 1978).

The amperometric sensors consume the compound they measure, but since microsensors are so small this effect can be ignored. The tip diameter of some types can be less than 1 μm , but for most studies ranges between 3 and 15 μm are common, so the sensors are of similar size as the microbes studied. The size of the sensor must be carefully chosen. Small sensors respond faster and disturb the local microenvironment less, but are more fragile than larger sensors. The size of the sensor is a compromise between robustness and spatial resolution desired. For soft and extremely active biofilms microsensors of 1–3 μm are ideal; for measurements in coarse sand, tip diameters of 300 μm are used. Also for such big sensors, the actual

sensing surface is ca 1 μm , the size is determined by the thick glass wall (Table 1).

Essential equipment

Microsensors can be used in the laboratory and in the field. They can function also under high pressure, and can provide direct data from deep sea environments. Typical applications are measurements of concentration profiles and concentration changes upon a perturbation at a defined location. Microsensors are always positioned by micromanipulators mounted on a stable, heavy stand. The micromanipulator is preferably motorized, and controlled by a computer that is also used for data-acquisition. One can determine the exact position of the sensor to the surface of the studied object, with help of a dissection microscope. For in situ use all electronic components must be packed in water-sealed pressure housings. The most reliable in situ profiler consists of a single cylinder with amplifiers and computer for data storage and motor control. The sensors are mounted on special plugs directly on the cylinder, which can be moved vertically along a rail in steps of 12.5 μm (or multiples of this) by an external motor, according to a preprogrammed protocol. It is powered by a battery and can operate up to 72 h, at a depth of up to 6,300 m.

Applications

Microsensors have been intensively used in studies on sediments, biofilms, and microbial mats (Kühl and Revsbech, 2000). The microscale distribution of substrates is a function of both mass transfer and local conversion rates, so if we have two of the phenomena quantified

Microsensors for Sediments, Microbial Mats, and Biofilms, Figure 2 Microprofiles of O_2 , pH and Ca^{2+} in calcareous sediments from a coral reef (Heron Island Australia). The effect of photosynthesis is demonstrated.

we can calculate the third: from the microprofiles and mass transfer we can determine the distribution of microbial activity (Berg et al., 1998; Gieseke and de Beer, 2004; Revsbech et al., 1986), and from the microprofiles and the local conversion rates we can determine the mass transfer rates (de Beer et al., 2006; de Beer et al., 2004). The latter possibility is rather rarely considered, but the most direct way to determine advection and areal conversion rates in advection-dominated sediments.

Calcification is for geology a highly relevant (micro) biological process (see Chapters *Microbial Biomineralization*; *Stromatolites*). The large background calcium concentrations of ca 8–10 mM make it difficult to determine calcification rates from a mass balance. With microsensors it is possible to measure micromolar concentration changes in seawater, in time or over distance, and thus to study the relation between (de)calcification and metabolic activities (*photosynthesis* and respiration). In Figure 2 the effect of light on coral reef sediments (Heron Island, Great Barrier Reef) is demonstrated: by photosynthesis the oxygen concentration peaks in the photic zone, due to CO_2 fixation the pH shifts up and calcium carbonate precipitates (concentration minimum). In the dark (right panel) calcium diffuses out of the sediment. The photic layer in which these processes occur is less than 5 mm thick.

Microsensors are extensively used to study photosynthesis in microbial mats (Hoehler et al., 2002; Polerecky

et al., 2007; Revsbech et al., 1983; Wieland and Kuehl, 2000; Wieland et al., 2005) (see Chapter *Hypersaline Environments*), (de Beer and Schramm, 1999; de Beer et al., 1994b; Santegoeds et al., 1998; Schramm et al., 1996, 1999), in sediments (Revsbech, 1983; Sweerts, 1990; Sweerts and de Beer, 1989; Sweerts et al., 1990). Using diver-operated microprofilers well-controlled in situ measurements are possible (Weber et al., 2007; Ziebis et al., 1998). However, the most exciting applications are autonomous deployments on sites too remote or too harsh for human guidance: (1) direct in situ measurements during tidal cycles give insight in transport processes in permeable intertidal flats (de Beer et al., 2004; Røy et al., 2007; Werner et al., 2006a,b), (2) the in situ measurements in the deep sea supply physiological data communities associated with gas hydrates and high pressure volcanism (de Beer et al., 2006; Glud et al., 1993, 1994; Wenzhöfer et al., 2001a,b; Wenzhöfer and Glud, 2002). It is thinkable that some sort of microsensors will be used in future exploration of other planets.

Summary

Microsensors can measure the microenvironment of dense and highly active microbial communities on the scale of microbes. Microsensors are used in field studies and in controlled laboratory experiments. As the sensors are very small they do not disturb the structure or the

pore-water chemistry, allowing precise, rapid, and online measurements of steady-state microprofiles, or concentration dynamics upon a perturbation. Both types of measurements are useful for high spatial resolution studies on the distribution of microbial activities, and on studies on mass transfer phenomena.

MOLAR-TOOTH STRUCTURE

Brian R. Pratt
 University of Saskatchewan, Saskatoon, SK, Canada

Definition

Molar-tooth structure is a synsedimentary, combined deformation and early diagenetic feature occurring in calcareous strata of mainly Precambrian age. It consists of arrays of closely spaced, sharply defined, upright veins, and subordinate horizontal sheets and spheroids composed of calcite microspar. Veins are vertically to obliquely oriented, discontinuous, typically strongly squashed or crumpled, and often brecciated.

Geological age

Molar-tooth structure (MTS) was first named in 1885 from its appearance on limestone bedding planes in the Mesoproterozoic Purcell Supergroup (= Belt Supergroup in USA.) along the border between southwestern Canada and adjacent northwestern Montana. Almost all occurrences are in Mesoproterozoic to late Neoproterozoic (Ediacaran) strata, representing a 1 billion-year time span from about 1,600 to 600 Ma, but there are several examples noted from the Paleoproterozoic and one from the Neoarchean (James et al., 1998; Pratt, 1998b; Shields, 2002; Meng and Ge, 2002). Importantly, a few Phanerozoic cases have also been reported (Figure 1c; Pratt, 1982; Rossetti, 2000).

Geobiological implications

Organisms and organic matter have been alleged to be implicated in MTS formation in various ways. Its rarity

after the Neoproterozoic has been ascribed generally to substrate modification by animals. However, the drastic reduction of MTS occurrences took place before the known appearance of infaunal invertebrates and, instead, Shields (2002) saw the decline as due to changes in the chemistry of seawater, especially a decrease in CaCO_3 saturation caused by a drop in atmospheric pCO_2 . There may have been an evolutionary control on the shape and mineralogy of lime mud, leading to the precipitation of granular lime mud which was thus prone to fluidization (Pratt, 1998b, 2001). Pratt (1998b) postulated that the rheology of carbonate sediment altered with the changing nature of organic matter and the microbiota brought about by the “Cambrian explosion.” Biomarkers in late Neoproterozoic examples represent cyanobacterial, anaerobic bacterial, and eukaryotic algal precursors in the sediment (Kuang et al., 2004). According to some interpretations, MTS was originally void space created by CO_2 generated by the biodegradation of organic matter

Molar-tooth Structure, Figure 1 (a) Lime mudstone riddled with molar-tooth structure (MTS) veins (dark): initially sparse and upright, passing upward to dense and strongly oblique, thence, in the upper two thirds, to upright but markedly crumpled and tilted. George Formation, Muskwa Group (~1.6 Ga), northern British Columbia. (b) Mudstone with three generations of MTS and erosion surfaces. First-generation veins in lower part are fragmented and reworked while second-generation veins are upright. Lowest erosion surface (vertical arrows) is cusate around upright veins, with vein fragments collected in gutter at left. Overlying mudstone contains third-generation veins that are variably oriented. Second erosion surface (oblique arrows) truncates veins; vein fragments are collected in gutter at left and on horizontal surface at right. Overlying cross-laminated grainstone contains a fourth generation of rare upright veins. George Formation. (c) Wackestone (dolomitic areas light gray) with crumpled veins (whitish). Coronach Member, Herald Formation Red River Group (late Ordovician), 14-26-6-11W2 (2,565.5 m), southern Saskatchewan (see El Taki and Pratt, 2009).

(Furniss et al., 1998; Pollock et al., 2006) or by CO₂-clathrate destabilization (Marshall and Anglin, 2004). James et al. (1998) suggested that a surface microbial mat sealed the sediment. If not physicochemical, precipitation of CaCO₃ crystals in the veins (Pollock et al., 2006) or as sediment grains before being fluidized (Pratt, 1998b, 2001) may have been triggered by dissolved organic molecules, nucleated on organic particles, or induced by photosynthesis.

Shape

MTS occurs mostly in both clean and argillaceous subtidal lime mudstones (Figures 1a–c, 2a and b), but a few are in shales (Figure 2c). Individual vein arrays crosscut up to ~0.5 m of sedimentary bedding; locally, they can comprise more than 50% of the host rock. Veins are discontinuous, range from fairly uniform to variable in width up to ~5 mm along their length, and typically exhibit tapered terminations. Although more or less straight to gently curved in some beds, mostly veins are strongly squashed or crumpled. The whole array may be tilted in one direction. On bedding planes, veins describe variably continuous subparallel, crisscrossing, or irregularly reticulate lines. The upper and lower surfaces of horizontal veins match, indicating that they are dilatational sheet cracks. Crudely spheroidal blobs are up to ~1 cm across. Two crosscutting episodes of vein formation are common, and they typically show differing degrees of deformation. In some argillaceous and silty units, as many as four consecutive phases of vein generation can be delineated, with each containing progressively less calcite and more

terrigenous particles, and consequently appearing less and less distinct from the matrix.

The matrix usually shows soft-sediment deformation especially in the form of small-scale folding. Typically, the matrix along with the enclosed MTS was deformed plastically together. Veins may be dislocated and the segments shingled in both vertical and horizontal directions, but they are also often stretched, boudinaged, or smeared. In many cases, a subsequent event caused the still plastic matrix to be deformed around veins that had become stiff due to calcite cementation, which also resulted in brecciation of the veins. After consolidation of the matrix, a further phase of deformation caused small mode I cracks in the veins but little displacement. These features are evidence for variably directed compressional, tensile and shear stresses that were imposed often repeatedly during the separate rheological evolution of both components.

Seafloor erosion affected many beds with MTS. The more resistant veins commonly protruded above the substrate, and vein segments and fragments were winnowed out and concentrated into interbedded intraclastic grainstones (Figures 1b and 2b). In a so far unique case, cross-lamination in vein fills indicates that they were exhumed and reworked by waves before cementation (Bishop and Sumner, 2006).

Composition

Locally MTS consists of micrite. However, in most cases it is composed of interlocking, equant, inclusion-free microspar crystals 7–15 µm across (Figure 3a). Back-scattered electron microscopy and cathode-luminescence reveal that in some examples these crystals consist of

Molar-tooth Structure, Figure 2 Thin section photomicrographs of molar-tooth structure (MTS) (light gray); scale bar same for all. (a) C_{org}-rich mudstone with densely packed squashed and broken veins, overlain by distorted, laminated mudstone with tilted and crumpled upright and subhorizontal veins. George Formation. (b) Dolomitic mudstone with two crosscutting generations of horizontal and squashed upright veins. In middle, grainstone lamina (composed of micrite peloids and grains of MTS) is crossed by veins and part of its interparticle porosity is filled with microspar. I-5 unit, Atar Group (~1.1 Ga), Mauritania. (c) Slightly calcareous shale with spheroidal and crumpled upright veins. (Vertical crack in center is an artifact.) Chamberlain Formation, Belt Supergroup (1.45 Ga), central Montana.

Molar-tooth Structure, Figure 3 (a) Thin section photomicrograph of calcite microspar in pod-shaped molar-tooth structure (MTS) and smeared, variably distinct, horizontal veins, and stringers; isolated microspar grains are also dispersed in shale matrix. Chamberlain Formation. (b) Back-scattered electron photomicrograph showing microspar mosaic with euhedral mud-sized cores (dark gray). Cores are rhombs and less commonly multifaceted crystals. Monteville Formation, Transvaal Supergroup (~2.6 Ga), South Africa (see Bishop and Sumner, 2006, fig. 9C; photograph courtesy of J. W. Bishop). (c) Thin section photomicrograph of squashed and shingled veins crossing argillaceous lime mudstone overlain by sandstone. Veins contain quartz silt and very fine-grained sand (whitish grains near the sandstone and sourced from it; those elsewhere are authigenic quartz crystals). Helena Formation, Belt Supergroup, northwestern Montana.

well-sorted rhombs and multifaceted euhedra with calcite cement overgrowths (Figure 3b; Pollock et al., 2006; Bishop and Sumner, 2006). These cores may be the original mud particles or a product of syndimentary recrystallization. Similar grains occur in the matrix mudstone or shale. Microspar in MTS is typically uniform in size but locally there is variation that describes crude wall-parallel lamination; indistinct shear veins or cracks can be detected in some examples. In some units the MTS is recrystallized to pseudospar.

Where veins penetrate interbedded siltstone or sandstone layers the microspar may contain silt or fine sand plus minor amounts of clay (Figure 3c; Pratt, 1998b, 1999; Bishop and Sumner, 2006). MTS may grade into dikelets and thin sills of injected silt and sand of the kind that have been termed “syneresis” cracks (Pratt, 1998a; cf. Tanner, 1998; Shi et al., 2009).

The calcite in MTS exhibits $\delta^{13}\text{C}_{\text{PDB}}$ values in the range of about -1.5‰ to 3.5‰ , which are similar to those in co-occurring sedimentary carbonate particles (Frank and Lyons, 1998; Pratt, 1998b; Marshall and Anglin, 2004; Bishop et al., 2006; Kuang et al., 2007).

Formation

For more than a century, the enigmatic nature of MTS was tolerated but largely ignored. Because fragments of MTS comprise sedimentary particles, it was eventually recognized as having formed intrastratally just below the sediment–water interface. Some geologists presumed MTS to be a fossil algal or microbial object. Later it was accepted as a deformation feature involving substantial shrinkage of the host sediment – although not due to desiccation because there is no evidence for associated subaerial exposure.

Pore-lining cement fabrics are absent in MTS even though they are present in co-occurring grainstones. Nevertheless, it is still debated whether or not MTS was initially a system of cavities, in which case CaCO_3 precipitated later as tiny crystals inside them (Fairchild

et al., 1997; Furniss et al., 1998; Pollock et al., 2006; Bishop and Sumner, 2006; Bishop et al., 2006). The presence in MTS of sand, silt, and clay impurities as suspended particles, clusters of grains, or seams is difficult to reconcile with this interpretation.

The possibility that MTS began as voids forced open by bubbles of CO_2 passively generated by the oxidation of organic matter in the sediments is unlikely because of the extreme amount of organic matter required, the shallow-water, oxidizing depositional setting, the linear to reticulate shape of vein arrays, the evidence for concomitant sand and silt injection, and the complex nature of the stresses demonstrated by accompanying physical deformation (Pratt, 1999). Because of the tropical sedimentary environment of host limestones, the involvement of CO_2 -clathrates is implausible. In most units, the absence of closely associated high-energy features is further evidence against the possibility of void opening by wave-induced loading (Bishop et al., 2006).

Pratt (1998b) explained MTS as a seismically induced deformation feature of calcareous sediment possessing unique geotechnical properties for which modern analogues are lacking. By this model, cyclic loading during earthquakes caused elevated fluid pressure and loss of shear strength in the muddy sediment. During abrupt dewatering, veins, sheet cracks, and spheroidal pockets were jacked open by the injection of granular lime mud that was segregated from the sediment. Examples where more than 50% of limestones consist of MTS indicate that a substantial proportion of the lime mud was mobilized. However, shaly host rocks still contain poorly defined seams and residual disseminated calcite grains that did not find their way into veins. Incorporated sand and silt show that dewatering and injection were both downwardly and upwardly directed. Spheroids formed where dewatering was localized and fluids did not escape to the surface. All this caused a striking shrinkage of the matrix and compaction of upright veins. As shaking proceeded,

they were squeezed, sheared, and stretched in different directions. After cementation of the mud infill, subsequent events deformed the matrix again, generated more veins, and brecciated the first set of veins, until the sediment was too stiff to deform further. Indeed, in almost every case, distortion of MTS and the matrix testifies to differential rheologies and progressive evolution from liquefaction through plastic deformation to brittle failure, as would be expected if affected by repeated earthquakes during dewatering and early diagenesis. A similar seismic model has been invoked for sand and silt dykelets (syneresis cracks), except that synsedimentary cementation was not involved (Pratt, 1998a).

MOONMILK

Joachim Reitner
University of Göttingen, Göttingen, Germany

Synonyms

Bergmilch; Lac lunae; Lac montanum; Mannmilch; Mondmilch; Montmilch; Mundmilch

Definition

Moonmilk is a carbonate deposit that occurs within various subterranean systems. Moonmilk has a white to gray color and, in contrast to rigid cave deposits (*speleothems*) such as stalactites and stalagmites, exhibits a soft, muddy texture of microcrystalline aggregates. These aggregates are mainly composed of calcite, and to a lesser extent of aragonite, monohydrocalcite, hydromagnesite, sulfates, and nitrates (Martínez-Arkarazo et al., 2007; Richter et al., 2008; Cañaveras et al., 2006; Borsato et al., 2000). The calcite shows an aragonite-like needle form (“lublinite”), which is normally associated

with soil bacteria. The crystal needles have a diameter of about 0.1 μm and a length of ca. 8–10 μm . The name “moonmilk – Mondmilch” is derived from the name of a cave, “Mondmilchloch,” located at the Pilatus mountain (Emmental Alps, Switzerland) (Fischer, 1988).

Geobiological implications

Moonmilk differs in many aspects from the traditional cave carbonates such as stalagmites and stalactites (Moore and Sullivan, 1997; Bögli, 1978). Its formation is strongly influenced by microbial activity, as suggested by the presence of microbial aggregates, biofilms, and/or fungal mycelia (Cañaveras et al., 1999, 2001, 2006; Borsato et al., 2000; Gadd, 2004; Burford et al., 2003). Moonmilk is a result of (1) microbially mediated weathering and *microbiocorrosion* of carbonate host rock under highly humid conditions and (2) microbially mediated reprecipitation of various carbonate minerals. After dissolution of the mineral components, the residue exhibits high amounts of organic remains. Besides many fungal and actinomycetes, the bacterium *Macromonas bipunctata* plays a major role in the formation of moonmilk. *M. bipunctata* is a lophotrichous, heterotrophic and strictly aerobic betaproteobacterium that has been classified as a colorless sulfur bacterium capable of oxidizing sulfide (Dubinia and Grabovich, 1984). Within *extracellular polymeric substances (EPS)* of *M. bipunctata* and further microbes, calcite seed nuclei are formed to precipitate “lubinite” moonmilk crystals. *M. bipunctata* was originally described as *Pseudomonas bipunctata* by Gicklhorn (1920) and renamed by Utermöhl and Koppe (1924).

MUD MOUNDS

Marta Rodríguez-Martínez
 Universidad de Alcalá, Alcalá de Henares, Madrid, Spain

Synonyms

Biodebital mound; Carbonate mounds; Carbonate mud mound; Lime mud mound; Microbial mound; Mudbank; Reef mound; Stromatactis mounds

Definition

Mud mounds are biosedimentary buildups, part of the reef system and are dominated by fine-grained carbonates (up and more than 50% of rock volume), which form heterogeneous polygenetic matrix-supported fabrics (stromatolitic, thrombolitic, leiolitic, fenestral, laminar, reticulate, stromatactoid, etc.). These fabrics are composed of both allomicrites and automicrites (abiogenetic, biogenetically induced, and biogenetically controlled). Production and accretion mechanisms in mud mounds are varied and not always clear, but are associated with the activity of microbial benthic communities (in different degrees of participation). Metazoans, being important colonizers, can or cannot occur but never produce a primary skeletal framework. Mud mounds colonized the oceans from the Proterozoic times, and they grow up from deep aphotic basinal settings to shallow water platforms.

Evolution of the term mud mound

Probably, the core of the Silurian Wabash buildup (Indiana, EEUU) was the first carbonate deposit referred to in the literature as a “carbonate mud mound” and was described as a mound of calcisiltite containing crinoid, bryozoan, ostracode bioclasts, and stromatactis, but essentially no stromatoporoids or corals (Textoris, 1966). The Silurian mud mound facies were compared by Textoris with similar buildups reported from other parts of the world (Devonian of Canada, Carboniferous of Europe and EEUU).

When reefs turned mud mounds

In the 1960s, the lack of a recognizable skeletal framework in these buildups pointed out their differences with the “classical” reef idea. During some years, most works on mud mounds were focused on the study of their scarce fauna and few were mentions to the origin of the carbonate mud, paradoxically the main component. Wilson (1975) extended in his book the definition and denomination of “lime mud mound” to many other Phanerozoic buildups, which were seen as dominated by detrital, bioclastic micrites with minor organic boundstone and *perceived to accumulate both through hydrodynamic processes and in situ organic production*. Thus, during the 1970s, the origin of the matrix was explained by the baffling theory: the carbonate mud, externally produced, was baffled by metazoans (crinoids, bryozoans, sponges, etc.). The role of early submarine cementation was also taken into consideration to explain the stabilization of mud mound depositional slopes. Baffled micrites and subsequent cementation was the proposed origin; thus, mud mounds were compared with very different types of Holocene buildups: shallow-water seagrass mudbanks and deep-water coral lithoherms.

When some mud mounds turned into microbial reefs

From the 1970s to the 1980s, some fabrics and textures present in the mud mounds were related with “cryptalgal” and other biosedimentary structures as stromatolites and thrombolites (Monty, 1976; Pratt, 1982). The mud mound matrix could be now bound, trapped, and precipitated by the activity of microorganisms (“blue-green algae” – cyanophytes and cyanobacteria).

From then, the source or origin of the carbonate mud, the matrix problem, will be the leitmotiv in the study of mud mounds. Bosence et al. (1985), from the recent carbonate mounds from Florida Keys, proposed three mud mound models based on the relation between the external and the internal sediment (carbonate mud) supplies in the mound: export, import, and self-sufficient models, respectively. From the 1970s and clearly in the 1990s, mud mounds began to be seen as “self-sufficient” mounds, and the role of microbial communities in their construction gained more importance (Tsien, 1985; Lees and Miller, 1985; Camoin and Maurin, 1988).

James and Bourque (1992) proposed a conceptual classification of reefs and “mounds,” where mounds are *those structures which were built by smaller, commonly delicate and/or solitary elements in tranquil settings*. They differentiated three types of mounds: “microbial” mounds, “skeletal” mounds, and “mud” mounds. Microbial and skeletal mounds are grouped into “biogenic mounds” because they are organically controlled, whereas the term “mud mound” was restricted by the authors to those *formed by inorganic accumulation of mud with variable amounts of fossils*. The authors pointed out that *the division between biogenic mounds and mud mounds depends on the nature of the accumulation/construction controls, not on the percentage of fossils*.

One of the main outstanding questions concerning the mud mounds is related to the modes of formation of the carbonate mud matrix and their recognition. The increase in the number of studies on microbial carbonates and their formation and fabric classifications (Kennard and James, 1986; Burne and Moore, 1987; Riding, 1991) led to new horizons in the matrix problem. Fabrics and geochemical signatures from automicrites of recent cryptic microbialites and controls in their formation (Reitner, 1993) were found to be similar to those recorded in Cretaceous and Jurassic mud mounds (Neuweiler, 1993; Keupp et al., 1993; Reitner et al., 1995; Leinfelder and Keupp, 1995). Thus, modern automicrites began to be used as modern counterparts of some mud mound end products.

Some authors began to use the term mud mound in a descriptive nongenetic way as *carbonate buildup consisting of more than 50% of mud and/or peloidal mud* (Reitner and Neuweiler, 1995), having depositional relief, and forming part of a polygenetic and continuum spectrum ranging from “biodetritral” to “microbial” mud mounds (Bosence and Bridges, 1995). Pratt (1995) considered mud mounds as ecologic reefs because they possess “rigid frameworks” produced by both microbial activity and syndimentary cementation.

Last formal definition of mud mound has been given by Riding (2002), as *carbonate mud-dominated (micrite and fine-silt) deposits with topographic relief and with few or no stromatolites, thrombolites, or in-place skeletons*. Riding added that *the deposits can be organic and/or inorganic in origin and it can be difficult to distinguish their origins*.

General features

Mud mounds have varied external forms; the term mud mound is used here not in a morphological way due to the fact that not all of them are mounds or dome-shaped; they can be tabular-shaped and can occur as isolated massive bodies or as stacked or amalgamated bodies, spreading over kilometers. The biggest mud mound complex is the Waulsortian mudbank from Ireland.

They could develop as a high syndimentary relief and show depositional dips from 10° up to 50°, can be or cannot be flanked by bioclastic limestones, and grow up from

basinal to platform settings. Mud mounds are composed mainly of fine-grained carbonate-matrix-supported fabrics, which are called, depending on the classification schemes followed, mudstones, wackestones, biomicrites, etc. These carbonate muds are texturally and genetically varied. The presence of cavities can be a characteristic feature in some mud mounds. Their macrobiota are diverse and can be important volumetrically in some mounds, although they never constitute a skeletal framework.

Types of carbonate muds

Carbonate muds are formed by pure aphanitic micrites and/or mixture of silt-sized calcite particles (up to 62 μm) as peloids. Then, they can be texturally grouped into aphanitic and peloidal micrites. Both types occur separately, or there is grading between them; they also occur as neomorphosed microspars. Microstructurally, they appear as dense and/or clotted/grumular/spongiostromic microfabrics, which constitute at mesoscale, stromatolitic,

thrombolitic, fenestral, and/or cryptalgal/cryptomicrobial/leiolitic fabrics (summarized in Riding, 2000).

The carbonate muds can be classified in relation to the *locus* of their production. The muds externally produced and later imported into the mound are named allomicrites (Figure 1). They are stabilized at mound surface by mound biota (eukaryotes and prokaryotes) through baffling, trapping, and/or binding mechanisms and early cementation.

The in situ produced carbonate muds are named automicrites. They are formed through abiogenic, biologically induced, and biologically controlled mechanisms (summarized in Flügel, 2004). The biologically related mechanisms are known as nonenzymatically and enzymatically controlled carbonates. Mud mounds seem to be specially dominated by the nonenzymatically carbonate production of automicrites via nonliving substrates (organomineralization of the organic matter derived from decaying organisms) and/or via metabolic processes (by heterotrophic, chemolithotrophic, and phototrophic bacteria and cyanobacteria). In the first case, the

Mud Mounds, Figure 1 Relationships between the mud mound biota and carbonate mud stabilization and production processes.

resulting automicrites are known as organomicrites. The automicrite production occurs at mound surface as well as at subsurface.

The mud mound system comprises both soft (allomicrites and automicrites) as well as firm/early indurated carbonate muds (automicrites), which can suffer from reworking processes (chemical, physical, and/or biological ones) resulting in parautochthonous muds. These secondary muds or the next successive generations of in situ muds, therefore, resemble a mixture of previous ones. This system should be analyzed as a continuous series of processes of automicrite production, allomicrite input, and internal reworking.

The filling of mound cavity system records many of the last mud mound synsedimentary episodes: (1) the entry of allomicrite by gravity or currents, (2) the colonization by cryptic biota, (3) production of automicrites, (4) reworking processes, and (5) the early marine cementation phases as well as burial-related phases.

So mud mounds have polygenetic carbonate mud-dominated fabrics resulting from automicrites production, allomicrites input, and recycling processes (Figure 1). But some microfabrics have been related at the same time with different types of biogenic as well as abiogenic processes, and discriminating between some processes and their products is not always possible.

Mud Mounds, Figure 2 Microbial mat-based model for accretion of mud mounds and development of cavities. (Modified from Pratt, 1982.)

Biota

Dominant invertebrate macrofossils on mud mounds were suspension feeders as pelmatozoans, bryozoans, and sponges – siliceous and calcareous types, although others such as brachiopods, molluscs, and arthropods could be sporadically important. Solitary and colonial corals occasionally occurred on mud mound records as well as calcareous algae, but they were much less common (not as colonizers of the shallow-water mud mound phases). Others such as benthic foraminifera and polychaete worms also occurred as part of the mud mound biota from the Carboniferous times. In general, the biota of mud mounds was mainly dominated by heterozoan assemblages.

In mud mounds, excluding the evident microbial fabrics (stromatolitic, thrombolitic and others), the main signal or product of microbial activity is hidden in the carbonate mud (biogenic automicrites) and in some authigenic mineralizations (iron pigments, Fe/Mn surfaces, framboidal pyrites, etc.). There is also direct evidence of calcified microbes (*Girvanella*, *Renalcis*, *Epiphyton*, *Bacinella*, *Rivularia*-like forms, etc.), and most of them have been interpreted as cyanobacterial fossils. Other evidence of microbial activity is the presence of unidentified filament-rich microfibrils, filaments and spherulites as moulds or casts, and peloids.

Sponge–bacterial assemblages have also played an important role in the initiation and first stages of many mud mound developments (early cementation of sponge tissues is related with the activity of symbiotic bacteria as well as the organomicrite production through the decaying of their tissues).

Cavities

There is a wider spectrum of cavity types in mud mounds (stromatactis, zebra, irregular, and sheet-like shapes). Probably, the most famous are the stromatactis, with smooth, flat base and irregularly digitate roofs, matrix-supported in general, although some can be partially or totally sheltered by remains of fossils. Filled with centripetal marine fibrous cement crusts and varied internal sediments (allomicrites and automicrites), stromatactis were abundant in Paleozoic mud mounds, especially from the Ordovician–Mississippian interval.

The origin of stromatactis has been largely debated, and today it remains controversial. Several hypothesis has been used (summarized in Flügel, 2004, 194 p.), which can be grouped in “organic” (recrystallized fossils, related with decaying organism, burrowing, etc.) and “inorganic” theories (dissolution, collapse, internal erosion between submarine crusts or bioclasts, dewatering and compaction of the muds, recrystallization, enlargement of preexisting cavities, presence of gas hydrates, etc.). In the organic cases, there are two models: the cryptalgal/microbial mat model and the sponge model.

The microbial mat model was initially proposed by Pratt (1982) to explain the mud mound accretion and its

final observed fabrics (Figure 2). The fabrics and the resulting cavities were the result of the combination of three variables: (1) the distribution of the microbial mat, (2) the rate of sediment loading onto the mat, and (3) the degree of winnowing. The distribution of the microbial mat (laterally continuous or in patches) produces the resulting fabrics (laminar or reticulate, respectively). The winnowing of the unconsolidated sediment between the microbial bounds and cemented sediment produces the cavities.

In the sponge model (Bourque and Boulvain, 1993), the cavities are formed by the partial collapse of the sponge body as result of early diagenetic processes through four stages (Figure 3): (1) zone of the living community, (2) zone of sulphate reduction, (3) zone of oxidation of ferrous iron, and (4) zone of marine cementation. In the living surface, the mud is trapped by sponges and/or produced by microbial activity. Below the surface, the microbial decay of sponges occur; part of the sponge body and the mud are cemented, and other sponge parts are in collapsed state; the later internal erosion of the unconsolidated material produces the open cavities. A few meters

Mud Mounds, Figure 3 Sponge model for the Paleozoic red stromatolitic mud mounds. (Modified from Bourque and Boulvain, 1993.)

below, in the ferrous iron oxidation zone began the incipient marine cementation of these cavities forming the stromatactis.

Types of mud mounds through the Phanerozoic record

The classification and distribution of mud mounds through the record depend on the “mud mound versus reef concept” of almost each researcher and thus remain controversial in several aspects. Mud mounds have existed from Proterozoic times and through the Phanerozoic record (see reviews by Monty, 1995; Pratt, 1995), and important growth episodes occurred in early Cambrian, late Devonian, and Mississippian times. Cambrian to Ordovician mud mounds (Figure 4) were characterized by different fabrics and assemblages (stromatolitic, thrombolitic, and massive fabrics with calcimicrobes, and cambrian archaeocyathid/sponge-calcimicrobial

assemblages). From the Ordovician to the Mississippian, some of the carbonate mud-rich buildups, which typify this interval, have been regarded as the classical massive mud mounds with abundant stromatactis (Figure 4) as the ‘red stromatactis mounds’ (Recif Rouges-type mound) and the Waulsortian mudbanks (Figure 5a and b). Clear microbilite-related fabrics (stromatolites and thrombolites) are extremely rare in classical mud mounds, although they show other nonskeletal reef frameworks (calcimicrobial and biocemenstones *sensu*, Webb, 1996), as well as filaments and some characteristic features (clotted, peloidal micrites, and fenestral microfabrics). The parallel diversification of skeletal mound macro- and micro-biota produced more varied metazoan–microbialitic assemblages. One of the most persistent through the mud mound record is the sponge–microbialitic association, very common in Jurassic mud mounds as well as in the deeper initial stages of many Paleozoic mounds. Early Cretaceous is considered the last significant moment of organomineralic mud mound development (Neuweiler et al., 1999), although

Mud Mounds, Figure 4 Distribution of mud mounds through the geologic record. (A) Precambrian to Quaternary time divisions. (B) Distribution and relative importance of nonenzymatic reef frameworks (from Webb, 1996), characteristic also in mud mounds. (C) Distribution of (1) microbial and (2) biotrital mud mounds. (Modified from Bosence and Bridges, 1995.) (D) Distribution of stromatactis and stromatactoid cavities, the size of the bar represents their relative importance in mud mounds. (E) Interval distribution of the main typologies of mud mounds.

Mud Mounds, Figure 5 Classical mud mounds. (a) Close view of a Devonian Recifs Rouges-type mound, Beauchateau Quarry, Belgium. (b) Carboniferous Waulsortian mudbank, Waulsort, Belgium.

other authors mentioned that the latest mud mounds are Miocene (Pratt, 2000).

Ecological zonation models

The Récifs Rouges-type mounds and the Waulsortian mudbanks are probably the most famous and are well known as “classical mud mounds” (Figures 4 and 5) Devonian (Frasnian) mounds from Belgium show a shallowing upward succession from deep basal greenish-grey shales through their mud mound facies: red lime mudstones to wackestones with stromatactis, pink wackestones with millimeter stromatactis to crudely bedded grey wackestones to packstones, and bindstones, and their associated biota. Similar facies (red stromatactis mounds) and assemblages have been found in other mud mounds through the Paleozoic record (Bourque, 1997). The carboniferous Waulsortian mudbanks of Belgium show a four grain-type assemblages related with the growth of these mounds from deep subtidal, aphotic to photic conditions. A depth-related phase model was recognized by Lees and coworkers (summarized in Lees and Miller, 1995) and applied to Waulsortian mudbanks of Europe and North America. Bourque (1997) compared Récifs Rouges-type mounds from Silurian of Canada and Devonian of France and Belgium with carboniferous mounds from Algeria and the Waulsortian mudbanks model and established an ecological zonation model formed by four benthic communities zones (Figure 6): (1) the sponge zone, (2) the fenestellid–sponge zone, (3) the delicate skeletons–sponge zone, and (4) the delicate skeletons–microbial encrusters zone.

Controlling factors

Today, many parameters about the initiation, accretion, and spread of many mud mounds seem to be enigmatic. However, some others begin to be more clear.

Locations of some mud mounds have been related with submarine cold seeps, vents, faults, halokinetic and argilokinetic settings, and local antecedent topographic irregularities, have been associated to nutrient-enriched areas (by endo-, down- and/or up-welling currents), and could be also related with stratified basin waters and fluctuating oxygen minimum zone. Many of them grew up into aphotic to disphotic depths (more than 200 m); however, they could reach and colonize the euphotic zone. Some grew at lower sedimentation rates and/or during sedimentary starvation during TST episodes, although this is not a general trend for all of them. Most of these factors are oceanographic and/or tectonically basin-related parameters and could co-occur together in many cases.

Those factors (biological and chemical parameters) associated with the carbonate mud precipitation related with eukaryotes and prokaryotes should be taken into consideration:

- Production of acidic organic macromolecules (AOM) and an increase in carbonate alkalinity via (1) bacterial heterotrophic pathways (ammonification and sulphate reduction), (2) carbonate, and (3) silicate weathering. AOM and high alkalinity favor the organomicrite production in microbialites and mud mounds (Reitner and Neuweiler, 1995).
- Extracellular polymeric substances (EPS)-biomineralization of microbial mats and biofilms.
- Calcification of cyanobacteria.

Conclusions

Mud mounds are considered mainly as nonenzymatic carbonate deposits that formed a polygenetic and very continuous record of buildups through the Phanerozoic and reached a maximum development during the Paleozoic times. They are of considerable importance not from an economic point of view (hydrocarbon reservoirs, major mineral host-rock and base deposits, ornamental rocks) alone. In fact, they represent an excellent record for the study and establishment of (1) the interactions between the marine microbial and nonmicrobial benthic communities (paleoecologic and paleoenvironmental parameters), (2) marine carbonate production models (mud mound factory), and (3) proxies in palaeoceanographic reconstructions (nonenzymatic carbonates are formed in equilibrium with ambient sea water).

Mud mounds are characterized by different modes of carbonate mud production (abiogenic, biologically induced, and biologically controlled automicrites) and sedimentation input (allomicrites). The key of mud mounds understanding lies behind here: to recognize and differentiate between the automicrite and allomicrite relationship and their contribution to the mud mound accretion.

METAGENOMICS

Wolfgang Liebl
 Technische Universität München,
 Freising-Weihenstephan, Germany

Definition

Metagenomics is a research discipline that uses molecular biology methods to acquire, analyze, and interpret sequence data and/or functional data from the metagenomes (the collectivity of genomes) present in the environmental samples, without the need to cultivate the organisms in the samples. Related methodologies are so-called metatranscriptomics and metaproteomics that focus on the collective transcriptomes and proteomes, respectively, rather than on the genomes.

Introduction

Microorganisms constitute major life forms on earth with respect to cell numbers and total biomass, and fulfill essential functions in global element cycles. It has been estimated that the earth's biosphere harbors at least two to three orders of magnitude more prokaryotic cells ($4\text{--}6 \times 10^{30}$) than the number of plant and animal cells combined. The total carbon fixed in prokaryotic cells amounts to $3.5\text{--}5.5 \times 10^{17}$ g of C which is 60–100% of the estimated total carbon in plants (Whitman et al., 1998).

For many decades since the beginnings of microbiology, research in this field has depended on the isolation and cultivation of individual microorganisms (best illustrated for the area of medical microbiology with the work of Robert Koch on the isolation and characterization of pathogenic bacteria in monocultures, leading to the Koch's postulates) or well-defined syntrophic consortia, and the subsequent in-depth analysis of pure cultures. Until today, microbiological research with traditional cultivation and

subsequent chemical, genetic, and physiological characterization has led to the description of roughly 10^4 bacterial and archaeal species deposited as pure cultures in microbial culture collections. However, in the course of the past 2 decades, it has become more and more evident that the microbial diversity in most aquatic habitats, soil, as well as oceanic and terrestrial subsurfaces is enormous (Amann et al., 1995; Hugenholtz et al., 1998; Quince et al., 2008; Sleator et al., 2008) and that at least at present the majority (>99%) of microorganisms in many complex habitats are not cultivated by using standard techniques (Amann et al., 1995). Thus, it must be acknowledged that the number of described species contrasts by orders of magnitude with estimates about the number of prokaryotic taxa on earth which may amount to 10^6 – 10^8 distinct genospecies (Simon and Daniel, 2010). Metagenomics, a relatively young research discipline, can aid in the detection and acquisition of data about this vast majority of uncultured microorganisms. For this methodology, which importantly is independent of cultivation, the collectivity of genomes (the metagenome) present in a given environmental sample is extracted and subjected to completely random or gene-targeted sequence analysis (Figure 1).

Although bacteria and archaea normally are unicellular, they usually occur as highly diverse but often poorly characterized consortia in their natural habitats. Individual environmental samples can contain a breathtaking prokaryotic diversity. For example, the numbers of different molecular species or operational taxonomic units (OTUs) in soil samples could be over 10^6 (Curtis et al., 2002). Statistics-based predictions for a specific Canadian soil sample range from 2×10^4 to 1.4×10^5 taxa (Quince et al., 2008). Highly interesting, based on taxonomy assessment results from deep-sea hydrothermal vent samples and statistical follow-up considerations, even samples from extreme environments – which often are believed to contain only limited biodiversity due to the extreme conditions – have revealed enormous microbial biodiversity, for example, 3×10^5 bacterial taxa at one specific sample site (Quince et al., 2008). These numbers illustrate the problems one faces to reach near-complete metagenomic datasets for complex natural habitats with today's analysis techniques. Thus, even with high-throughput methods, it is difficult if not impossible to generate a complete microbial inventory of a habitat including also most of the rare taxa. However, the methods available do allow the reliable

Metagenomics, Figure 1 Flowchart summarizing steps of environmental meta-analysis.

identification of the abundant taxa that presumably account for the major biogeochemical conversions.

Uses and applications of metagenome analysis

One major advantage of metagenomic analysis is that one can obtain a wealth of genetic information about organisms that live together in more- or less-complex communities, most of which cannot be cultivated with today's standard techniques. It can be used for extremely diverse purposes, such as the analysis of fundamental aspects of microbial community structure, function, and adaptation in environmental microbiology, but also to explore and exploit the microbial genetic, metabolic, and enzymatic diversity space for the development or improvement of biotechnological processes. Examples for the application of metagenomic techniques in geobiology are the analysis of microbial communities in rock material, sediments, aquifers, as well as in biofilms, on rock surfaces or in subsurface caves and mines, etc. It must be stressed that it is of utmost importance for most metagenomic studies to comprehensively record the sample-associated metadata (the data about the data), like date and position of sampling, physical and chemical characteristics, etc., as has been pointed out by Wooley et al. (2010).

Principally, metagenome analysis can be applied to any kind of habitat, irrespective of the complexity of the microbial communities present. For low-diversity habitats, high-throughput metagenome sequencing can yield a comprehensive overview of genetic information present and can even allow the near-complete or complete assembly of whole prokaryotic genomes, which was nicely shown for the organisms present in acid mine drain fluids (Tyson et al., 2004) or community genome sequencing of an anammox bacterium (Strous et al., 2006). However, the more diverse the community, the higher the sequencing and/or screening effort has to be to arrive at results that cover as comprehensively as possible the target genes of interest present in the sample. In some cases, it is possible to reduce the amount of work and costs by choosing a more specific than a completely random metagenome analysis. For example, if the main interest of a study lies in the analysis of genes involved in a certain metabolic trait (like breakdown and utilization of a specific substrate), one can try to enrich for the corresponding genes by carrying out enrichment cultures wherein the growth of organisms which display this metabolic trait is favored (e.g., by supplying the said specific substrate as the sole carbon source). Enrichment cultivation also has the advantages that (i) more cell material becomes available and that (ii) less organic and inorganic contaminating compounds from the original habitat sample that may interfere with DNA isolation yield and quality are present. An alternative is to enrich for genomic DNA or RNA from microorganisms with a certain substrate utilization capability by feeding a natural microbial community with ^{13}C - or ^{15}N -labeled substrate and then to isolate and process only the heavy nucleic acid that stems from

organisms that utilized the added ^{13}C - or ^{15}N -substrate and incorporated the label into their nucleic acids (stable isotope probing) (Friedrich, 2006; Neufeld et al., 2007). Using enrichment cultures to preselect for microorganisms with certain physiological traits has been successfully done in several cases (e.g., Entcheva et al., 2001) and may be of advantage especially for very complex microbial communities, but it has to be kept in mind that any kind of cultivation step before DNA isolation can result in dramatic changes in community composition and diversity.

Assessment of phylogenetic and functional diversity

Sequence analysis of conserved marker genes, usually 16S rRNA genes, is widely used for community diversity assessment. To this end, 16S rRNA gene sequences can be amplified with PCR directly from metagenomic DNA samples, followed by cloning into appropriate vectors and sequence analysis. Also, the sequences of conserved marker genes (rRNA genes, but also protein-encoding marker genes) can be retrieved from large sequence datasets compiled by large-scale random sequencing of metagenome DNA and then used for phylogenetic community composition assessment (von Mering et al., 2007).

Recently, massively parallel sequencing specifically of rRNA gene fragments amplified from metagenomic DNA has become possible by the use of the 454 Life Sciences (Roche) high-throughput tag pyrosequencing technology (Huse et al., 2008), but due to the fact that read-length limitations presently only allow the sequencing of incomplete rRNA gene fragments, this technology is suited for the trustworthy phylogenetic assignment at the phylum level but is not as reliable at the genus or species level. Nonetheless, this method allows interesting insights into the affiliation of microorganisms from complex communities to the large phylogenetic lineages, and technological improvements pertaining to the read lengths will surely allow more precise analyses at the genus or species level in the near future.

Bioinformatic tools are available for the comprehensive phylogenetic tree calculation from alignments of conserved marker sequences, for example, the ARB software package (Ludwig et al., 2004). Also, other sequence information than merely phylogenetically conserved genes available from large metagenomic random DNA sequence datasets can be used for diversity assessment. In the past years, various software tools have been developed that are useful for the so-called taxonomic binning of such sequence information (see Simon and Daniel, 2010). While some algorithms work on the basis of oligonucleotide sequence frequencies (composition-based binning, e.g., PhyloPhytia, TETRA; Teeling et al., 2004; McHardy et al., 2007), which are known to vary between different genomes, others use comparative orthologous ORF analysis for this purpose (CARMA, MEGAN, Sort-ITEMS; Huson et al., 2007; Krause et al., 2008; Monzoorul et al., 2009). Importantly, however, since most of these

bioinformatic tools depend on genome sequences and annotations from the available reference genome databases, which presently cover only a minority of the (readily) culturable species (not to speak of the enormous uncultured species diversity present in nature [see above]), our present possibilities for the assignment of short metagenomic DNA sequences to microbial taxa are quite limited.

Current large-scale efforts to sequence the genomes of the prokaryotic species deposited in major microbiological culture collections (GEBA, a Genomic Encyclopedia of Bacteria and Archaea; <http://www.jgi.doe.gov/programs/GEBA/>; Wu et al., 2009) will surely dramatically improve the reference genome sequence database necessary for a more accurate phylogenetic assignment of metagenomic sequence fragments. Nevertheless, considering that there are still in some cases not a single, in other cases only very few cultured representatives for some deep-rooting phyla, severe limitations in our ability to reliably assign short metagenomic DNA sequences to phylogenetic taxa will remain at least in the near future.

Screening for genes in metagenomes

Metagenomic studies often include the screening of metagenomic libraries or metagenomic sequence datasets for genes of interest, for example, for genes encoding key enzymes characteristic for habitat-specific physiological traits, or for genes for biotechnologically relevant enzymes. Two fundamentally different approaches are used for this: the sequence-based approach and the function-based approach. Both methods have individual advantages and disadvantages and are explained briefly in the following.

The *sequence-based approach* uses in silico sequence mining, PCR amplification or hybridization methods to detect and isolate genes of interest. Metagenomic sequence datasets can be scored for fragments encoding orthologs of known genes deposited in the available reference databases. Various bioinformatic tools such as BLAST, Pfam, SEED, TIGRFAM, MEX, RAMMCAP, or MG-RAST are available which are helpful for the functional annotation of metagenome sequence data (see Simon and Daniel, 2010; Wooley et al., 2010). Another sequence-driven approach is to design degenerate PCR primers directed against conserved sequence motifs in a gene family of interest and to amplify partial ORFs from metagenomic DNA. The fragments can then be used to isolate the complete ORFs, for example, by using them as hybridization probes to identify clones or metagenomic DNA fragments containing the adjacent, missing ORF sequences, or by metagenome walking (see Simon and Daniel, 2010). Alternatively, DNA microarrays carrying oligonucleotides derived from consensus sequences of known genes have been used for the sequence-directed screening of a metagenomic library for a light, oxygen and voltage (LOV) domain blue light photoreceptor gene (Pathak et al., 2009). The major disadvantage of sequence-based gene detection is that this method depends on prior sequence information from known gene families.

Therefore, truly novel genes unrelated to the already known genes encoding for a given function cannot be identified with this approach.

In the *function-based screening approach*, clones from metagenomic libraries are subjected to activity-based assays that indicate the function of interest. The major advantage of this approach is that it allows the recovery of complete genes or gene clusters and of novel types of enzymes without any prior knowledge of the sequence. However, in order to work efficiently, the genes of interest, which often originated from uncultured microorganisms with unknown genetics and physiology, must be compatible with the expression machinery provided by the heterologous screening host with respect to transcription, translation, protein folding, and eventually secretion (Gabor et al., 2004). Therefore, the fraction of the existing enzymatic diversity that can be accessed via functional screening approaches is strongly influenced by the choice of the host organism used. The phylogenetic distance between the gene donor and the cloning/expression host may be crucial for the success of gene expression. Mostly, *Escherichia coli* is used to construct metagenomic libraries for functional screening, but it is clear that the expression of metagenomic genes can be severely biased in this host. Therefore, it is important to establish and improve an alternative host/vector systems in order to enhance the probability of detecting genes from metagenomic samples (Angelov et al., 2009; Steele et al., 2009; Uchiyama and Miyazaki, 2009).

Some restrictions and problems

Despite the power of metagenomic studies to unravel genetic information from microbes in communities that are not amenable to cultivation and in-depth characterization, a number of restrictions and problems remain, only some of which are listed hereafter.

Huge amounts of data are generated, especially in metagenome random sequencing projects. These data need to be generated, processed, and stored in a complex succession of steps. Special care must be taken with respect to library construction and sequencing quality. Exemplarily, the procedure of a metagenomic sequencing project is described by Kunin et al. (2008). A useful compilation of software tools for composition-based and similarity-based taxonomic binning, functional annotation of metagenomic data, and comparative metagenomics can be found in Wooley et al. (2010).

Interpretation of the sequence data and their connection with biochemical functions of biocatalysts remains a challenging task. The tools for ORF extraction from metagenomic sequence data and bioinformatics-driven function prediction are being improved constantly, but it is of course not feasible to check all gene function predictions experimentally, for example, by heterologous expression and biochemical analysis. Also, if only metagenomic DNA sequence data are available, it is unclear if the genes found are expressed at all. Thus, it has to be kept in mind that in many cases sequence data

obtained from metagenomes only indirectly point to (predicted) enzymes/pathways of the organisms in the sample. In future, performing metatranscriptomics and/or metaproteomics experiments in parallel with metagenomics can help to overcome this problem.

Also, linking phylogenetic and functional metagenomic data with the physiology of living microorganisms in the environmental sample is a crucial but not a trivial step for many studies attempting to correlate environmental data with a microbial community. Due to the species complexity in most microbial communities, it is only rarely possible to obtain assembled genomes. Even if conserved marker sequences point to close relatives of certain well-known microorganisms this does not necessarily prove that the organisms from which the metagenomic sequence information was derived have identical physiologies as the reference organisms. Also, some traits believed to be characteristic for certain phylogenetic groups of microorganisms can get lost by simple mutations. Still, it is possible to extract environment-specific gene fingerprints from unassembled random environmental DNA sequencing data that reflect known characteristics of the sampled environments, thus linking metagenomic sequence information with metabolic functions of the organisms present (Tringe et al., 2005).

Finally, since most conclusions reached from metagenome data analysis rely on comparative sequence analysis and thus are indirect, it will be important to develop and improve new microbiological cultivation and characterization techniques that also allow the cultivation and in vivo analysis of physiologically and quantitatively dominant microbial representatives within the studied communities.

Summary

Considering the enormous microbial diversity in most environmental samples on one hand and the current shortcoming of the microbiologists' ability to cultivate the vast majority of these organisms on the other hand, it makes sense that metagenomics has become one of the key methods to study the composition and functions of complex microbial communities. The rapid advance of massively parallel sequencing and high-throughput screening technologies will enable even faster and cheaper access to environmental sequence datasets in the future, but connecting the metagenomic data with the physiology of the microorganisms and the environmental data remains challenging, and it will be crucial that the development of experimental setups and bioinformatic tools keep pace in order to be able to derive meaningful conclusions from metagenomic sequence data.

Definition

Enzyme protein containing one or more metal cofactor(s).

Introduction

Metalloenzymes are enzyme proteins containing metal ions (metal cofactors), which are directly bound to the

protein or to enzyme-bound nonprotein components (prosthetic groups). About one-third of all enzymes known so far are metalloenzymes (see Holm et al., 1996 for a general overview). Besides enzymes, other metalloproteins are involved in non-enzyme electron transfer reactions (cytochromes), may act as storage (e.g., ferritin for iron) or transport proteins (e.g., transferrin for iron). In the latter groups of proteins, the metal storage is reversible and the metal is a temporary component. Also ribozymes, i.e., RNA molecules with enzyme function may contain structurally and/or functionally important metal ions (mostly divalent metal ions such as Mg^{2+}) and may be therefore termed as metalloenzymes in a broader sense (Sigel and Pyle, 2007).

Though primarily focused on enzyme proteins, i.e., proteins acting as biocatalysts in biochemical reactions, also important non-enzyme proteins (without catalytic activity in the strict sense) and their metal centers are discussed in this article.

In enzyme catalysis, transition metals are of special relevance due to their redox activity, and/or a high charge density, which allows the polarization of enzyme substrates. Vanadium, molybdenum, tungsten, manganese, iron, cobalt, nickel, and copper metal centers have been characterized so far; the metal atoms can occur in mono-, di-, and multinuclear centers with nitrogen, oxygen, and sulfur atoms of the polypeptide chain as possible ligands (Holm et al., 1996; Degtyarenko, 2000; Wilson et al., 2004; Table 1). For analysis of metal centers in proteins, spectroscopic tools for the investigation of small molecules are of relevance, namely electron paramagnetic resonance (EPR) or the related electron-nuclear double resonance (ENDOR) spectroscopy, electron spin resonance (ESR), resonance Raman or Mössbauer spectroscopy. Data obtained from X-ray protein crystallography are inevitable to locate the metal center and its ligands inside a protein molecule. Combination of proteomic approaches with technologies for elemental trace analysis (inductively coupled plasma mass spectrometry or ICP-MS) introduced tools for determination of the entire set of metalloproteins (the metalloproteome) and/or all trace metals (metallome) in an organism (Szpunar, 2005; Barton et al., 2007).

Metalloenzymes in early evolution

In early evolution, precursors of metal enzymes may have played a key role in catalytic reactions relevant for the synthesis of prebiotic macromolecules. According to the hypotheses originally postulated by Wächtershäuser, surface-bound iron, cobalt, nickel, and other transition metal centers with sulphido, carbonyl, and other ligands were catalysts involved in the synthesis of macromolecular compounds by carbon fixation, thus promoting growth of organic “superstructures” (Wächtershäuser, 1990). The metabolic type of this prebiotic scenario was chemolithoautotrophic, driven by the reducing potential of the outflow from deep-sea hydrothermal vents during

Enzyme protein containing one or more metal cofactor(s).

Introduction

Metalloenzymes are enzyme proteins containing metal ions (metal cofactors), which are directly bound to the

protein or to enzyme-bound nonprotein components (prosthetic groups). About one-third of all enzymes known so far are metalloenzymes (see Holm et al., 1996 for a general overview). Besides enzymes, other metalloproteins are involved in non-enzyme electron transfer reactions (cytochromes), may act as storage (e.g., ferritin for iron) or transport proteins (e.g., transferrin for iron). In the latter groups of proteins, the metal storage is reversible and the metal is a temporary component. Also ribozymes, i.e., RNA molecules with enzyme function may contain structurally and/or functionally important metal ions (mostly divalent metal ions such as Mg^{2+}) and may be therefore termed as metalloenzymes in a broader sense (Sigel and Pyle, 2007).

Though primarily focused on enzyme proteins, i.e., proteins acting as biocatalysts in biochemical reactions, also important non-enzyme proteins (without catalytic activity in the strict sense) and their metal centers are discussed in this article.

In enzyme catalysis, transition metals are of special relevance due to their redox activity, and/or a high charge density, which allows the polarization of enzyme substrates. Vanadium, molybdenum, tungsten, manganese, iron, cobalt, nickel, and copper metal centers have been characterized so far; the metal atoms can occur in mono-, di-, and multinuclear centers with nitrogen, oxygen, and sulfur atoms of the polypeptide chain as possible ligands (Holm et al., 1996; Degtyarenko, 2000; Wilson et al., 2004; Table 1). For analysis of metal centers in proteins, spectroscopic tools for the investigation of small molecules are of relevance, namely electron paramagnetic resonance (EPR) or the related electron-nuclear double resonance (ENDOR) spectroscopy, electron spin resonance (ESR), resonance Raman or Mössbauer spectroscopy. Data obtained from X-ray protein crystallography are inevitable to locate the metal center and its ligands inside a protein molecule. Combination of proteomic approaches with technologies for elemental trace analysis (inductively coupled plasma mass spectrometry or ICP-MS) introduced tools for determination of the entire set of metalloproteins (the metalloproteome) and/or all trace metals (metallome) in an organism (Szpunar, 2005; Barton et al., 2007).

Metalloenzymes in early evolution

In early evolution, precursors of metal enzymes may have played a key role in catalytic reactions relevant for the synthesis of prebiotic macromolecules. According to the hypotheses originally postulated by Wächtershäuser, surface-bound iron, cobalt, nickel, and other transition metal centers with sulphido, carbonyl, and other ligands were catalysts involved in the synthesis of macromolecular compounds by carbon fixation, thus promoting growth of organic “superstructures” (Wächtershäuser, 1990). The metabolic type of this prebiotic scenario was chemolithoautotrophic, driven by the reducing potential of the outflow from deep-sea hydrothermal vents during

Metalloenzymes, Table 1 Abundance of some metals in bacterial and algal organisms in g/100 g (dry weight) and some important key functions in enzymes (Barton et al., 2007)

Element	Algae	Bacteria	Some specific roles in enzymes
K	1.81	1.7	Protein stabilization
Ca	0.55	0.1	Protein stabilization
Mg	0.35	0.25	Protein stabilization
Fe	0.011	0.015	O ₂ transport, storage and/or activation; electron transport; superoxide breakdown
Mn	0.006	0.005	O ₂ evolution; peroxide and superoxide breakdown
Zn	0.001	0.005	Protein stabilization; hydrolytic cleavage
Cu	0.0007	0.001	O ₂ transport, storage and/or activation; electron transport; superoxide breakdown
Mo	0.0001	0.001	Oxygen transfer; N ₂ activation
Co	0.0003	0.001	Free radical reactions; nucleophil

**Metalloenzymes, Figure 1** Various metal centers (from Degtyarenko, 2000) (a) mononuclear iron center (nitrile hydratase), (b) mononuclear magnesium center (Ni-Fe-hydrogenase from *Desulfovibrio*), (c) dinuclear copper center (oxyhemocyanin), (d) polynuclear iron-sulfur center, (e) heme iron coordination (cytochrome P450), and (f) molybdopterin (sulfite oxidase).

the Hadean period. Namely, the acetyl-CoA biosynthetic pathway may be seen as a model for prebiotic energy metabolism, since in this pathway enzymes and other proteins with FeS and (Fe,Ni)S centers are involved (acetyl CoA-synthetase/carbon monoxide dehydrogenase, hydrogenases, ferredoxin); these metal centers are in principle the cubic Fe₄S₄ as well as (SNiS)(Fe₄S₄)(SFeS) units of greigite (Fe(II)Fe(III)₂S₄). Later on in evolution, the prebiotic metal centers became parts of peptides and, finally, defined proteins (Wächtershäuser, 1990; Russell and Martin, 2004). Among all metalloproteins, iron metalloproteins and, within this class, iron-sulfur proteins

are supposed to be the most important group and ubiquitous in organisms.

Besides FeS-centers, tetrapyrroles as metal-chelating prosthetic groups are interesting from the evolutionary viewpoint. Tetrapyrroles are as cyclic molecules (corrins and porphyrins; e.g., Figure 1e) ideal chelators of cobalt, copper, iron, manganese, and nickel. At the same time, the highly conjugated porphyrin molecules increase the catalytic activities of transition metal ions in electron transfer reactions by several orders of magnitude. Since porphyrins are present in all kingdoms of life, they must have evolved early in evolution, perhaps even in the

prebiotic state. As for FeS centers, the prosthetic groups are found in otherwise completely unrelated metalloproteins, such as methyl-coenzyme M reductase and chlorophylls (see below; Mauzerall, 1998).

Until the Paleozoic era, availability of bioessential transition metals changed by several orders of magnitude. Whereas Cu, Zn, Ni, and Mo concentrations increased in the ocean water, Co, Mn, and particularly iron decreased by several orders of magnitude during the Proterozoic eon (Anbar, 2008). These changes must have had an impact on the biogenic production of greenhouse gases such as nitrous oxide (Cu-dependant) or methane (Ni-dependant) and, hence, respective impact on global climate. The molybdenum cofactor (see below), in particular, plays a key role in the biological nitrogen cycle. It may even be speculated that molybdenum availability in oceans had a tremendous impact on early evolution. Under the reducing atmosphere, molybdenum was depleted in the proterozoic ocean, generating a “bottleneck” for the nitrogen cycle. The low availability of nitrogen must have had a retarding effect of total biomass production of all organisms (especially non-nitrogen-fixing eukaryotes), until the oxidizing atmosphere also provided high molybdenum availability and stopped nitrogen limitation (Zerkle et al., 2006; Anbar, 2008). Limited molybdenum availability may also have been overcome in part by (less effective) molybdenum-independent nitrogenases. The evolutionary history of the enzymes is, however, difficult to reconstruct. There is no phylogenetic evidence that these “alternative” nitrogenases preceeded the molybdenum-dependant enzymes (Raymond et al., 2004).

In recent oceans, though, most metal ions relevant for enzyme metal centers are just present in trace amounts in seawater, and/or form hardly soluble salts. Thus, most organisms utilize specialized chelating compounds, uptake and transport systems for metal ion intake.

Biomimetic metalloenzymes

Metal centers from enzyme proteins may give essential data for the design of biomimetic enzymes in bioorganic synthesis. Biomimetic metal centers from enzymes such as cytochrome oxidases (with Fe-porphyrin), catechol oxidase (based on Mn(IV)-complexes with *o*-aminophenol ligands), or hydrogenase (based, e.g., on six-coordinate Ni-Ru-centers with hydrogen as one of the bridging ligands for NiFe hydrogenase) reveal the biotechnological potential of catalysts derived from biological metal enzymes (Zbaida and Kariv, 1989; Chaudhuri et al., 2005; Song et al., 2005; Ogo et al., 2007).

Classification of metalloenzymes

Since metalloenzymes are found in all enzymes families, simple classification of metal-containing subgroups based on sequence similarities cannot be applied. Reasonable classification schemes are based upon the bioinorganic motifs (Degtyarenko, 2000; Figure 1), i.e., the metal atom and its ligands (Degtyarenko and Contrino, 2004).

Metal centers may be classified by the number of bound metal atoms as mononuclear (for one metal atom, Figure 1a and b) or polynuclear (more than one metal atom, Figure 1c and d) with endogenous ligands (i.e., the polypeptides of the enzyme molecule form a mostly polydentate coordination shell) or exogenous ligands (non-protein component of a conjugated protein such as heme or molybdopterin; Figure 1e and f).

The description given below is, for the sake of simplicity, based on the central atoms. It has to be kept in mind that different metal atoms can be bound to identical or similar bioorganic motifs (e.g., cobalt, copper, iron, magnesium, and nickel by porphyrins or corrins), and different motifs coordinate the same type of metal atom (e.g., either molybdopterin or Fe₇MoS₉ homocitrate cofactor for molybdenum; see below).

Metal centers in metalloenzymes and other metal proteins

Mononuclear iron proteins are oxidoreductases (e.g., aromatic amino acid hydroxylases, aromatic ring cleavage dioxygenases, Fe-superoxide dismutase, lipooxygenases, nitrile hydratase, and Rieske oxygenases), or involved in electron transfer (desulfuroredoxins, rubredoxins, and photosynthetic reaction centers). The amino acid ligands are mostly histidine and/or cysteine such as in nitrile hydratase with three cysteine residues and two amide nitrogens (Figure 1a). *Diiron carboxylate proteins* bind a coupled binuclear iron center using, e.g., four carboxylate and two histidine residues. Oxidoreductases (alkene hydroxylase, methane monooxygenase, and phenol hydroxylase), iron storage (bacterioferritin, ferritin), and oxygen storage/transport proteins are members of this group (hemerythrin, myohemerythrin).

Hemoproteins are characterized by an iron porphyrin as prosthetic group (Figure 1e). While four of the iron ligands are occupied by the porphyrin ring, the other two are used for binding of the protein. Hemoproteins are oxidoreductases (catalases, peroxidases), electron transfer proteins (cytochromes), or oxygen transport and storage proteins (globins) (Nordlund and Eklund, 1995; Que and Ho, 1996).

Iron-sulfur proteins are characterized by the presence of iron-sulfur clusters containing sulfide-linked di-, tri-, and tetrairon centers in variable oxidation states (Figure 1d). Iron-sulfur clusters are found in ferredoxins, NADH hydrogenases, dehydrogenases, cytochrome c reductases, nitrogenases, and other proteins. Proteins with iron-sulfur clusters have key roles in nearly all respiratory chains, either in bacteria and archaea or in mitochondria of eukaryotic organisms. Other functions include catalysis of stereo-specific isomerization of citrate to isocitrate (aconitase) in the tricarboxylic acid cycle or the redox-dependent gene regulation. The simplest iron-sulfur cluster type consists of two iron ions bridged by two sulfide ions and is coordinated by four cysteinyl ligands or by two cysteines and two histidins. The oxidized proteins

contain two Fe^{3+} ions, whereas the reduced proteins contain one Fe^{3+} and one Fe^{2+} ion. These species exist in two oxidation states, Fe(III)_2 and Fe(III)Fe(II) . Besides $[\text{2Fe-2S}]$, $[\text{3Fe-4S}]$, $[\text{4Fe-4S}]$, or $[\text{8Fe-7S}]$ clusters are known (Bertini et al., 1995).

Also in *copper-containing proteins*, several metal center types occur. Similar to iron proteins, copper proteins are involved in oxygen transport or activation processes and electron transport. *Type I copper centers* have a single copper atom coordinated by two histidine residues and a cysteine residue in a trigonal planar structure and a variable axial amino acid ligand. Type I proteins are, e.g., ascorbate oxidase, ceruloplasmin, laccase, nitrite reductase, auracynin, and azurin. *Type II copper centers* are square planar coordinated by N or N/O ligands (e.g., in galactose oxidase). *Type III centers* consist of two copper atoms (Figure 1c), each coordinated by three histidine residues (catechol oxidase, hemocyanins, tyrosinase). The *copper A center* in cytochrome c-oxidase consists of two copper atoms, coordinated by two histidine imidazole residues, methionine, carbonyl-oxygen, and two cysteine-S bridging the copper atoms. In cytochrome oxidase *copper B centers*, the copper atom is coordinated by three histidine imidazole residues. The *four copper atom center* of nitrous oxide oxidase is coordinated by seven histidine residues. The four centers are bridged by one sulfur atom. Besides cytochrome oxidase, also other copper proteins are frequently oxygenases or dioxygenases (monoamine-oxidase, laccase, caeruloplasmin, superoxide-dismutase, hemocyanine) (Adman, 1991).

Zinc proteins represent the third large group of metalloproteins, with one, two, or three zinc ions. Zinc ions in proteins are classified as catalytic, co-catalytic, and structural, where zinc is either directly involved in the opening or closing a chemical bond, or zinc acts in the catalytic reaction in concert with other metal ions, or zinc ions maintain structural integrity of the enzymes. Zinc ions in catalytic sites are generally coordinated to the side chains of three amino acid residues and a water molecule. In structural zinc sites, the ion is coordinated by four amino acid side chains in a tetrahedral symmetry. With a filled *d* orbital, zinc ions do not participate in redox reactions, but rather function as Lewis acids to accept a pair of electrons, which is favorable for reactions like proteolysis or the hydration of carbon dioxide. Important zinc-containing enzymes are the alcohol dehydrogenase (containing both a catalytic and a structural zinc site), metalloproteases, and carbonic anhydrases with catalytic zinc sites. Cocatalytic zinc sites are found in superoxide dismutases, phosphatases aminopeptidases, and β -lactamases. In alcohol dehydrogenases, the zinc catalytic site is responsible for binding of the hydroxyl group oxygen from the alcohol substrate by replacing the zinc-bound water molecule (Lipscomb and Sträter, 1996; McCall et al., 2000).

Nickel in metalloenzymes occurs as Ni-4Fe-5S (e.g., nickel-containing CO dehydrogenases), coordinated in a *tetrapyrrole complex* (e.g., in methyl-coenzyme

M reductase with glutamine as axial ligand) and as *dinuclear NiNi or NiFe complexes* (e.g., in hydrogenases and urease) or a $[\text{4Fe-4S}]^{2+}$ cluster bridged by a cysteine thiolate to a dinuclear NiNi center (acetyl-CoA synthase). Nickel-containing CO-dehydrogenases occur in anaerobic bacteria and archaea (CO-dehydrogenases from aerobic bacteria are molybdopterin enzymes), whereby CO is bound by the nickel atom and hydroxyl oxygen (from water) is transferred to the bound carbon atom. After CO_2 is released, nickel is reduced ($\text{Ni}^{2+} \rightarrow \text{Ni}^+$) and transfers two electrons to ferredoxin. In the methyl-coenzyme M-reductase reaction, methane and a heterodisulfide are generated from the substrate methyl coenzyme M that reacts with coenzyme B (7-thioheptanoylthreoninephosphate). In nickel-iron hydrogenases, nickel of the Ni-Fe center is coordinated by one apical and three equatorial S-cysteins. The Ni-Fe hydrogenases catalyze both H_2 evolution and uptake in vitro, with cytochromes acting as either electron donors or acceptors. Acetyl-CoA synthase catalyzes the reversible formation of acetyl-CoA from carbon monoxide, a methylated corrinoid protein and coenzyme A, and is complexed with a nickel CO dehydrogenase (Ermler et al., 1998).

Manganese in metalloenzymes may also act as a simple Lewis acid catalyst. Manganese (normally Mn(II)) can also be oxidized to the (III)- or (IV)-state in biological systems, which allows redox-cycling reactions. *Manganese metal centers* may be mono-, bi-, tri-, or tetranuclear. Mn-superoxide dismutases (SODs) exhibit *mononuclear centers* and are antioxidant metalloenzymes catalyzing the redox disproportionation of the superoxide radical, O_2^- . SOD decomposes the highly reactive superoxide anion by a two-step disproportionation reaction which generates oxygen hydrogen peroxide. The active site manganese is five-coordinate, with the metal ligands arranged in distorted trigonal bipyramidal geometry. Two known enzymes with *binuclear centers* are arginase and manganese catalase. Arginase catalyzes the conversion of arginine to urea and ornithine. The manganese ions are five- and six-coordinate, respectively, with square-pyramidal and (distorted) octahedral coordination symmetries. The metal centers are interconnected by a solvent-derived hydroxide and carboxylate residues. This metal-bridging hydroxide acts as nucleophile that attacks the arginine guanidinium carbon. Other binuclear manganese enzymes are aminopeptidase P from *Escherichia coli* and the dinitrogenreductase-activating glycohydrolase from *Rhodospirillum rubrum*.

One of the most important biochemical catalytic reactions in our biosphere, the oxygen-generating photolysis of water, is brought about by the *tetranuclear manganese cluster* in oxygenic photosynthesis of cyanobacteria, eukaryotic algae, and higher plants. In oxygenic photosynthesis, water is oxidized by a cluster of Mn ions. Light is captured by antenna chlorophyll and funneled to the primary reaction center, which contains chlorophyll (P680). The oxidized P680 first oxidizes a redox-active tyrosine. Subsequent oxidation of the Mn cluster occurs via this

generated tyrosine radical. The enzyme can exist in five oxidation levels, corresponding to various oxidation states of the cluster (Wiegardt, 1994; Yocum and Pecoraro, 1999; Carrell et al., 2002).

Molybdenum and *tungsten* enzymes catalyze basic metabolic reactions in the nitrogen, sulfur, and carbon cycles. With the exception of the nitrogenase cofactor, molybdenum is associated with the heterocyclic pterin derivative (molybdopterin) that contains a mononucleate center, coordinated to the thiols of the cofactor (Figure 1f). These *molybdenum-cofactor-containing (MoCo) enzymes* catalyze the transfer of an oxygen atom, derived from or incorporated into water, to or from a substrate in a two-electron redox reaction. Three classes of MoCo enzymes are now distinguished, represented by xanthine oxidase and sulfite oxidase families (with single pterin ligands and either ligand-Mo(VI)OS(OH) or ligand-Mo(VI)O₂(S-cys) cores), and DMSO reductase family (with two pterin ligands). The *nitrogenase molybdenum metal center* is not related to the pterin derivatives. In molybdenum nitrogenases, each Mo forms a part of a polynuclear cluster containing 1 Mo, 7 Fe, and 9 S organized into an elongated structure. Within the protein the terminal Fe of the cluster is coordinated by a cysteine residue, while the Mo is coordinated by a histidine residue and a homocitrate ligand.

Tungsten, which lies in the chromium group of the periodic system immediately below molybdenum exhibits similar chemical properties and is complexed in a similar way to the pterin cofactors as described for molybdenum. Due to the higher sensitivity of tungsten toward high redox potential, tungsten enzymes are found in (thermophilic) anaerobic bacterial and archaeal microorganisms (Hille, 2002; Williams and Fausto da Silva, 2002).

Cobalt is the central metal ion in the tertrapyrrol *corrin ring* in the coenzyme B₁₂. Similar to porphyrin rings, four coordination sites are provided by the corrin ring. The B₁₂-bearing enzymes catalyze either the transfer of methyl groups between two molecules or isomerization reactions, i.e., rearrangements of hydrogen atoms with concomitant exchange of a substituent (e.g., an hydroxyl group) between two adjacent carbon atoms in a molecule. In *non-corrin cobalt enzymes*, cobalt is complexed by aminoacids such as in nitrile hydratase (catalyzing the hydration of nitriles to amides; Kobayashi and Shimizu, 1999).

Vanadium occurs as V(III), V(IV), or V(V) in biological systems. The respective enzymes catalyze the two-electron oxidation of a halide by hydrogen peroxide. Besides the vanadium-containing enzymes, also heme-containing haloperoxidases and metal-free enzymes are known. In tunicates (ascidians) vanabin binds 20 V(IV) ions. However, the role of vanabins in vanadium accumulation by the ascidian has not yet been determined. In vanadium nitrogenases, vanadium, instead of molybdenum is present in a FeVCo-center (Michibata et al., 2003; Crans et al., 2004).

Though frequently not classified as metalloenzymes in the strict sense, numerous (enzyme) *proteins bind Na⁺ and*

K⁺ ions. The structures of Na⁺ and K⁺-complexes with proteins have a variety of coordination schemes and functions. Usual coordination numbers are five and six. Though the ions are not directly involved in catalytic steps, they activate numerous enzymes. Prominent examples are Na⁺-activated β -galactosidase or the K⁺-dependent activity of pyruvate-kinase and glycerol dehydratases (Page and Di Cera, 2006).

Specific *binding of calcium ions* frequently leads to conformational changes and increased protein stability. One large family of calcium-binding proteins is denoted *EF-hand proteins*, comprising a calcium-binding structural domain ("helix-turn-helix" motif). In an EF-hand loop the calcium ion is coordinated in a pentagonal bipyramidal configuration, by atoms of the protein backbone and side chains especially of aspartate and glutamate. Examples for EF-hand proteins are calmodulin and parvalbumin. In *non-EF-hand calcium-binding proteins*, the binding motifs are not conserved, such as α -lactalbumin and thermitase (Yang et al., 2002).

Also *magnesium* has a key function in activation and stabilization of enzymes. Isocitrate lyase and glutamine synthetase are two examples of Mg²⁺-activated metabolic enzymes. Enzymes catalyzing phosphorylation of proteins typically use magnesium chelates of ATP as cosubstrate. The bound Mg²⁺ serves to facilitate nucleophilic attack at the γ -phosphate of the ATP substrate. Phosphate and phosphoryl transfer reactions require Mg²⁺ as an essential cofactor. In chlorophyll molecules of photosynthetic reaction centers, magnesium ions are coordinated in a terrapyrrole ring system and to an axial *N*-histidin, *O*-aspartate, *O*-formyl-methionin, *O*-leucin, or water as ligands (Figure 1b; Cowan, 2002).

Conclusion

Since metal centers are present in all enzyme families, and enzymes with metal centers also catalyze a wide variety of different reactions, metal enzymes cannot be assigned to a special group of enzymes or proteins. Thus it is very likely that metal centers developed early in evolution and evolved in several different lineages. Since free transition metal ions are ideal catalysts for numerous reactions in organic chemistry (and biochemistry) at moderate temperatures, they appear to be the natural "precursors" of functional enzyme proteins. Peptides and proteins are, on the other hand, ideal chelators for metal ions. Thus, protein and metal partners may have easily come together frequently during evolution.

METALLOGENIUM

Joachim Reitner
 University of Göttingen, Göttingen, Germany

Definition

Metallogenium s.str. is a star-shaped enigmatic bacterium oxidizing Mn and iron. It preferentially lives in limnic environments.

Metallogenium is a relatively large (2–10 μ m) microorganism with bacterial affinities that concentrates manganese and iron oxides in significant amounts. The genus *Metallogenium* has not yet been assigned to any taxonomic group. The cells lack rigid walls and develop flexible, tapering threads from which new cells probably arise. The organism is therefore, star-shaped and is found in various facies, predominantly in limnic environments (Figures 1 and 2). The threads are often heavily encrusted with oxides of iron and/or manganese. The oldest

SUBSURFACE FILAMENTOUS FABRICS

Beda A. Hofmann

Natural History Museum Bern, Bern, Switzerland

Synonyms

Moss agate p.p.; SFF; Stalactitic minerals p.p.

Definition

Subsurface filamentous fabrics (SFF, [Figures 1–5](#)) result from the encrustation of microbial filaments with minerals in subsurface geological environments, followed by oxidation of organic matter ([Hofmann, 2007](#); [Hofmann and Farmer, 2000](#); [Hofmann et al., 2008](#)). Encrustations of fibrous minerals may yield similar fabrics, but a biogenic origin is indicated by evidence for high flexibility, and a low variability of the smallest diameter of the filamentous forms, typically 1–3 μm . SFF textures vary from delicate mineral webs to massive rocks containing enclosed filaments, depending on the degree of mineral precipitation after initial filament encrustation in voids. SFF are most commonly found in voids in volcanic rocks and in the oxidation zone of ore deposits rich in reduced elements (S, Fe), but also occur in paleokarst environments ([Baele, 1998](#); [Feldmann et al., 1997](#); [Kretzschmar, 1982](#)), Mississippi Valley-type base metal deposits ([Hofmann et al., 2008](#)), cavities in fossils ([Weitschat, 1986](#)), mineral veins ([Hofmann, 1989](#); [Reitner, 2004](#); [Trewin and Knoll, 1999](#)), and cavities in impact rocks ([Hofmann et al., 2008](#)). Many of these occurrences show low-temperature hydrothermal influences. Historically, SFF have aroused the interest of researchers because of their often conspicuous nature. Examples of long-known forms are particularly the so-called moss agates, for which various interpretations have

Subsurface Filamentous Fabrics, Figure 1 Characteristic example of pseudostalactitic SFF. Encrustation of mat-like, vertically draped fabric by goethite. From the oxidation zone of a sulfide deposit, Kintore open cut, Broken Hill, New South Wales, Australia. Scale in cm.

Subsurface Filamentous Fabrics, Figure 3 Image of filamentous forms enclosed within chalcedony in a fracture within a lithophysa in Tertiary rhyolite, Priday Ranch, Oregon, USA. Image width: 4 mm.

Subsurface Filamentous Fabrics, Figure 4 Filaments encrusted by iron hydroxides, associated to numerous folded mats, and enclosed by chalcedony. Host rocks are basaltic volcanics of Jurassic/Cretaceous age. This assemblage is known as moss agate. Image width: 18 mm. Arts Bogd Uul, Mongolia.

Subsurface Filamentous Fabrics, Figure 5 Filaments encrusted by iron hydroxides, enclosed in a single quartz crystal. Paleokarst within Devonian limestones (mineralization probably of Tertiary age), Hohenlimburg, Germany. Image width: 2.8 mm.

been brought forward (Bowerbank, 1842; Daubenton, 1782; Razumovsky, 1835). Similarities do exist with some types of dendrites (present in some moss agates) and speleothems. Many examples of “stalactitic” minerals (e.g., goethite, chalcedony, chrysocolla) were formed around filamentous centers with diameters in the order of microns, much too small for true speleothems the size of which is governed by the diameter of a water droplet (Hill

and Forti, 1997). Features discriminating SFF from similar fabrics are (Hofmann et al., 2008) (a) median width of filamentous substrate of $<5\ \mu\text{m}$ with narrow, near-normal distribution; (b) evidence of bending (e.g., U-loops) and aggregation to mat-like (biofilms), stromatolite-like, or rope-like fabrics; (c) filamentous cores show a high degree of irregular bending ($>0.5^\circ/\mu\text{m}$); (d) filamentous cores show many direction changes ($>10/\text{mm}$);

(e) association of SFF with or occurrence within SFF of other morphological bioforms such as fossil *Gallionella* or *Metallogenium*-like structures; (f) presence of vertically oriented elements (may resemble stalactites) resulting from mineral encrustation of filaments, filament strands, or mats while they are still flexible; and (g) inferred environmental conditions compatible with microbial growth, such as an abundant energy source and temperatures between ambient and $<120^{\circ}\text{C}$.

Types of organisms/substrates involved: The micro-morphology of SFF indicates that only filamentous micro-organisms are involved in their formation. Filamentous substrates of microbiological origin may include archaea, bacteria, and fungi. Some fabrics formed by encrustation of mineral fibers (these may be dissolved later) may show similar morphologies, but can usually be discriminated by evidence for characteristics typical of mineral fibers: Radial growth, variable fiber thickness, straight development, brittle behavior, and remnants of mineral fibers.

Conclusions

SFF represent a common, but often overlooked, type of biosignature from subsurface environments. SFF often display macroscopically visible fabrics that are easily recognizable and may be regarded as subsurface microbialites and the most conspicuous expression of the deep biosphere, representing in some ways an analog to stromatolites from surface environments. The very common occurrence in a wide variety of different rock types demonstrates that SFF are a common expression of subsurface life, wherever filamentous forms generate a large amount of biomass in relatively short time, allowing mineralization before organic filaments are destroyed. Organisms involved were chemolithotrophs (based on oxidation of Fe, S), but may also include heterotrophs living on chemolithotrophic primary producers. The formation in subsurface environments implies that no photosynthesizing organisms are involved. SFF-like features represent a target in the search for past life on Mars (Hofmann, 2007), as they might potentially be found in nearly all rock types.

ORIGINS OF THE METAZOA

Daniel J. Jackson
 University of Göttingen, Göttingen, Germany

Synonyms

Animals

Definition

Metazoans – heterotrophic, multicellular organisms that possess eukaryotic cells.

Heterotrophs – organisms that must ingest organic carbon to support growth, unlike plants that are autotrophic and can use light to photosynthesize organic compounds.

Evolutionary concepts

A major event in the time line of Earth's history was the evolution of multicellular animal life, known scientifically as the Metazoa (Knoll and Carroll, 1999; Knoll et al., 2006; Budd, 2008; Love et al., 2009; Xiao and Laflamme, 2009). Metazoans possess eukaryotic cells which contain a distinct membrane bound nucleus, nuclear material (DNA) packaged into multiple linear chromosomes, membrane bound organelles, and modes of cellular division distinct from that of Bacteria and Archaea (Cooper and Hausman, 2009). Metazoans are primarily set apart from plants (also multicellular eukaryotes) in being heterotrophic, and in lacking a rigid cell wall (Campbell et al., 2008).

While all other forms of life (Bacteria, Archaea, and plants) display extensive genetic and metabolic diversity (Venter et al., 2004), the metazoans through 600+ million years of evolution (Peterson et al., 2008) display the greatest variety of locomotory habits, behaviors, and morphologies. Indeed, a fundamental feature of the Metazoa is the morphological diversity displayed by the 35+ (Collins and Valentine, 2001) major groups of animals that constitute the Kingdom Animalia (Carroll, 2001).

Metazoan morphological diversity is essentially generated by two means. Firstly through an ability of

a collection of cells to accurately communicate with one another during the process of development, and secondly for members of that collection of cells to adopt fates with distinct functions. This is most clearly conceptualized when considering the process of metazoan development. Typically, unicellular gametes (sperm and egg cells) fuse to form a zygote (a fertilized egg), which then divides to produce a multicelled embryo and eventually a reproductively mature adult (Gilbert, 2006). During this process, undifferentiated embryonic cells become progressively specified to a particular cell fate (e.g., muscle, neuron, skin, gonad, and eye). Without cell fate specification, tissues (e.g., muscle), organs (e.g., hearts), and organ systems (e.g., digestive system) and the variety of functions that these collections of cells fulfill would not develop (Arendt, 2008).

Evolutionary changes to the metazoan developmental program are ultimately responsible for generating diversity in the adult phenotype. This realization has fuelled the growth of the field of evolutionary-developmental biology (Carroll, 2005). Comparisons of the genes that regulate different metazoan developmental programs now holds the exciting promise of explaining on a molecular level how metazoan morphological diversity is generated (Martindale et al., 2003; Matus et al., 2006). Additionally, recent developments in high-throughput DNA sequencing technologies have seen the completion of a variety of metazoan genomes (King et al., 2008; Putnam et al., 2008; Chapman et al., 2010). These large-scale datasets allow exhaustive comparisons to be made between disparate animal phyla, and deepen our understanding of the genetic innovations that accompanied the diversification of metazoan life.

Related to these efforts are attempts to understand how metazoan life first arose. This requires that we accurately understand how metazoan and pre-metazoan groups are evolutionarily related, and calls on the field of

Origins of the Metazoa, Figure 1 A phylogenetic tree represents a hypothesis regarding the evolutionary relationships of a given set of organisms. Speciation events (indicated by an arrow) generate new lineages of organisms that in turn speciate to generate new "sublineages" thereby increasing diversity. This simplified phylogenetic tree summarizes a recently proposed hypothesis (Pick et al., 2010) that suggests the last common ancestor of the Metazoa (indicated by the red circle) was a sponge-like animal that was descended from a choanoflagellate-like organism.

Origins of the Metazoa, Figure 2 The expansion of metazoan life primarily took place during the early and pre-Cambrian. Trace fossils and the soft-bodied remains of Ediacaran fauna are of uncertain phylogenetic affinities and therefore may, or may not, be ancestral life forms to those that inhabit the world today. However, the abundance of well-preserved specimens from Cambrian strata indicates that both the majority of modern day animal groups had been established during this time, and that the widespread adoption of various biomineralization strategies accompanied this diversification. (Reprinted with permission from Marshall, 2006.)

phylogenetics (Felsenstein, 2004). Although phylogenetics was arguably born over 150 years ago with Darwin's publication of the *Origin of Species* (Darwin, 1859), our understanding of metazoan relationships is far from settled, and remains an exciting and dynamic field of scientific research which now benefits from modern techniques in molecular biology (high-throughput DNA sequencing) and super computing (Stamatakis et al., 2008). Arguably, the current and most widely accepted

theory of the evolutionary origins of the Metazoa (based on a recent meta-analysis of DNA sequence data from a large collection of metazoan groups), maintains that sea sponges (phylum Porifera) are the most ancestral-like metazoan, with choanoflagellates (a primarily unicellular eukaryotic organism) representing the closest non-metazoan cousin (Figure 1; Pick et al., 2010). This theory is attractive because it is conceivable that a choanoflagellate ancestor once formed a colony of

individuals (modern choanoflagellates are known to do this), which then evolved into a primitive sponge, the first metazoan. However, because the Metazoa has origins dating back 600+ million years thus obscuring many of the phylogenetic signals used to infer kinship, and our understanding of the ways in which the mechanisms of molecular evolution operate are still being developed, competing theories should also be considered (Dunn et al., 2008; Schierwater et al., 2008).

Exactly when the first metazoan arose, and what it looked like remain topics of intense research. It is clear that approximately 542 million years ago (MYA), well after the birth of the Metazoa (Wray et al., 1996; Wang et al., 1999; Xiao and Laflamme, 2009), there was a period in the evolution of animal body plans that saw the generation of an unsurpassed diversity of phenotypes (Figure 2; Knoll, 2003a). Because of the rapid generation of this diversity, and the geological period in which it occurred, this evolutionary radiation has come to be known as the “Cambrian Explosion” (Gould, 1989; Marshall, 2006), and is typified by the sudden appearance in the fossil record of a range of biologically mineralized structures (Butterfield, 2003; Knoll, 2003b; Budd, 2008). While the underlying causes of this widespread adoption of biomineralization strategies is also an area of active research, likely candidates are changes to ocean calcium levels (Brennan et al., 2004), increased genetic potential (Peterson et al., 2009), and ecological factors such as increased predation pressure (Bengston and Yue, 1992). Satisfyingly, recent molecular estimates of early metazoan divergence times using molecular clocks (Bromham, 2008) have been shown to agree with paleontological data (Peterson et al., 2008).

Summary

Contemporary metazoans consist of animals representing a wide range of body plans ranging from the relatively simple sponges, cnidarians (jellyfish and corals), and ctenophores (comb jellies) through to more complex organisms such as snails, worms, insects, and vertebrates. Metazoan diversity has universal origins that lie in, or even prior to, the Cryogenian 635–850 MYA, with a watershed in metazoan evolution recognized as being in the early Cambrian (542 MYA) by which time most modern, and now extinct, metazoan body plans had been established. The last common ancestor of the Metazoa is likely to have shared morphological and genetic similarities with modern day sponges. Recent advances across a range of scientific fields are constantly forcing scientists to revise the evolutionary relationships of animals at all levels, but a clearly resolved and robust metazoan tree of life is gradually emerging.

METEORITICS

Mark A. Sephton

Imperial College London, London, UK

Definition

Meteorites are fragments of extraterrestrial material that fall on the Earth's surface. Most meteorites are parts of asteroids propelled into Earth-crossing orbits by relatively recent collisions in the asteroid belt, initiated by the gravitational effects of Jupiter's orbit. Relatively small numbers of meteorites originate from larger objects such as the Moon and Mars. The Earth acquires 10^2 to 10^3 t of such material each day, but only 1% or less arrives in pieces large enough for identification and recovery (Dodd, 1981). The surface of the meteorite usually melts and emits a glowing tail and a trail of smoke, but the interior of the meteorite is unaffected by passage through the Earth's atmosphere and remains at the temperature of interplanetary space.

Collection of meteorites

“Falls” are meteorites that have been observed to fall and were subsequently collected; “finds” are meteorites that were not seen to fall. Before the 1970s, the total number of known meteorites amounted to less than 1,000 falls and 1,706 authenticated finds. Since then, it has been recognized that certain parts of the Earth's surface preserve and concentrate meteorites. To date, tens of thousands of meteorites have been collected from the Antarctic ice. Similar numbers of meteorite fragments have also been collected from hot deserts. Most recently, telescope and camera network surveys have produced meteorites with photographed fireballs allowing the calculation of their orbits and assignment to a particular source within the solar system (Bland et al., 2009).

Chondrites

About 85% of the meteorites observed to fall on the Earth are chondrites, conglomerate rocks with an overall elemental composition similar to the Sun, if the loss of the most volatile elements is ignored. When their near solar makeup is considered alongside radiometric ages of 4.56×10^9 years, it becomes clear that chondrites are rocks formed during, or shortly after, the birth of the Sun.

The record in chondrites

Their status as some of the earliest formed solids in the solar system combined with a lack of subsequent processing ensures that chondrites represent a valuable record of extraterrestrial environments. Contributing regions include interstellar space, the solar nebula and the asteroidal meteorite parent bodies.

Carbonaceous chondrites

Of all the chondrites, the carbonaceous chondrites are considered the most primitive and these objects represent an enthralling window back in time providing views of the earliest solar system (Figure 1). The name “carbonaceous chondrite” is highly descriptive as these meteorites contain a carbon-rich matrix composed primarily of clay minerals, oxides, and organic matter, and most contain spherules of silicate glass termed chondrules.

Classification of carbonaceous chondrites

The carbonaceous chondrites are classified according to their primary and secondary characteristics (Figure 2). The primary classification (CI, CM, CR, CO, CV, CK)

Meteoritics, Figure 1 The Murchison carbonaceous chondrite.

reflects the original properties of the meteorites such as bulk chemistry and mineralogy. The label is derived from the carbonaceous chondrite accepted as the type specimen, for example, CI = Ivuna. The secondary numerical classification reflects petrographic type, which indicates the extent and type of alteration that the meteorite has undergone on its parent body.

Carbon in meteorites

The carbon in carbonaceous chondrites is present in several forms and each has its specific source region(s) (Table 1; Sephton et al., 2003). Materials like silicon carbide and graphite condensed from the atmospheres of stars that existed long before our Sun. Nanometer-sized diamonds also originate as condensation products of stellar outflows as well as from catastrophic supernova explosions. Carbonate minerals were formed in the early solar system as aqueous alteration took place on asteroids. Yet all these components are quantitatively subordinate to the main carbonaceous material in carbonaceous chondrites – organic matter.

Types of organic matter in meteorites

Much of our current understanding of meteoritic organic matter has come from investigations of the Murchison carbonaceous chondrite, approximately 100 kg of which fell in Australia in 1969 (Figure 1). Not all of the organic molecules in meteorites are present in the same form. A minor portion of the organic matter in meteorites is present as small “free” molecules, including various hydrocarbons and the biologically useful amino acids and carboxylic acids (Figure 3), but the majority of organic matter in the carbon-rich meteorites is present as a highly cross-linked organic network or “macromolecular material”.

Meteoritics, Figure 2 The classification system for carbonaceous chondrites.

Free compounds

Amino acids

The amino acids found in meteorites have attracted a great deal of attention owing to their role as building blocks for proteins. The search for amino acids in meteorites accelerated in the 1960s (Degens and Bajor, 1962; Kaplan et al., 1963) following reports of microfossils in certain samples (Claus and Nagy, 1961). Amino acids were discovered, but these initially promising results were later found to be the result of terrestrial contamination. It was only when the organic-rich Murchison meteorite fell and was rapidly analyzed that both protein and, importantly, nonprotein amino acids were found in this fresh sample (Kvenvolden

et al., 1970). Today it is known that the amino acids in Murchison are present at around 60 ppm. Compounds containing two through eight carbon atoms exist and they exhibit several features, which suggest that they are not terrestrial contaminants but are extraterrestrial and nonbiological or “abiotic” in origin. The meteoritic amino acids display broad structural diversity, a decline in abundance with increasing molecule size, and the presence of unusual and even unique molecular configurations.

A particular characteristic of amino acids is chirality or handedness. One chiral form rotates the polarized light to the left and is termed levorotatory or “L,” while the other form rotates the light to the right, and is called dextrorotatory or “D.” Chirality is important for theories that link extraterrestrial organic matter with the origin of life, because terrestrial biology preferentially generates L-amino acids whereas abiotic reactions generally have no preference and produce racemic mixtures with equal amounts of L and D forms.

The discussion of whether amino acids in meteorites were racemic (with equal amounts of L and D forms) or nonracemic (with a preference for one or the other) began in the 1950s and continued through the 1960s, (e.g., Mueller, 1953; Nagy et al., 1964) but early results implied that the dominance of L forms was caused by terrestrial contamination and analytical artefacts. Yet following the fall of Murchison in 1969, four protein and seven

nonprotein amino acids were found to be racemic (Kvenvolden et al., 1970, 1971). More modern analyses have reinvigorated the debate over the racemic nature of meteorite amino acids and a slight L-excess in both protein and nonprotein amino acids has been reported (Engel and Nagy, 1982; Pizzarello and Cronin, 2000).

Proposed mechanisms for producing this L-excess in meteoritic amino acids rely on selective destruction of the right-handed form of the amino acids. Currently, popular hypotheses involve ultraviolet circularly polarized light from a neutron star or reflection nebulae (Bailey, 2001; Bonner and Rubenstein, 1987). It is a necessary consequence of this theory that at least some amino acids were already formed in interstellar space so that preferential destruction of D-amino acids could take place. The recent detection of the simplest amino acid, glycine, in interstellar spectra supports this assertion (Kuan et al., 2003).

Carboxylic acids

Carboxylic acids are another type of biologically useful molecule found in meteorites. In life, they are a convenient and compact store of energy and are common cell membrane molecules. Carboxylic acids in Murchison contain between two and five carbon atoms and display complete structural diversity, a general decrease in abundance with increasing carbon number, and an equal concentration of branched and straight-chain isomers (Lawless and Yuen, 1979; Yuen and Kvenvolden, 1973). The monocarboxylic acids are present in a much higher concentration (332 ppm) than the amino acids and are the most abundant solvent extractable compounds. A structurally diverse suite of dicarboxylic acids containing up to nine carbon atoms are also present in much smaller amounts (26 ppm) (Lawless et al., 1974).

Hydroxyacids

Hydroxycarboxylic acids (or hydroxyacids) in carbonaceous chondrites contain up to nine carbon atoms and are structurally diverse and present in concentrations of 15 ppm (Peltzer and Bada, 1978). Intriguingly, the hydroxyacids correspond in structure to the more abundant amino acids suggesting that some hydroxy and amino acids may have been produced together on the parent asteroid. The relevant chemical reaction is known as the Strecker-cyanohydrin synthesis. Hydrogen cyanide and aldehydes combine in aqueous solution to produce hydroxyacids but if ammonia is also present then the products become amino acids.

Sugar-related compounds

Collectively, sugars and their related compounds are called polyhydroxylated compounds or "polyols." They are compounds containing a number of hydroxyl (OH) groups attached to their carbon skeleton. Sugars are

important biologically as a source of energy for organisms and, when combined to form larger molecules, they can act as food stores and give structural support. Experiments in the 1960s detected polyols in carbonaceous chondrites, but terrestrial contamination was implied (Degens and Bajor, 1962). More recent experiments on Murchison have discovered a number of sugar-related compounds (sugars, sugar alcohols, and sugar acids) in similar abundances to the amino acids (Cooper et al., 2001). The Murchison polyols display many of the features of extraterrestrial compounds. Progressively larger polyols become less abundant, display almost complete structural diversity, and contain some terrestrially rare compounds implying an abiotic source.

Aliphatic and aromatic hydrocarbons

Short aliphatic molecules in Murchison are present in amounts of 1.4 ppm and display many nonbiological features, which imply they are indigenous to the meteorite, such as structural diversity and a decrease in amount with increasing molecule size (Yuen et al., 1984). Aromatic hydrocarbons, in free form are present in carbonaceous chondrites at around 30 ppm (Pering and Ponnamperna, 1971). Compound sizes range from one to seven aromatic rings with the smaller compounds generally being most abundant (Sephton et al., 1998).

Amines and amides

Amines are derivatives of ammonia (NH₃) where hydrogen atoms are replaced by other structures. In Murchison, amine concentration is 8 ppm, amounts of individual amines decrease with increasing carbon number and structural diversity is observed with almost all amine isomers with up to five carbon atoms present (Pizzarello et al., 1994).

Two possible sources of the amines in Murchison have been proposed: they may be directly inherited from the presolar molecular cloud, an assertion supported by the detection of methylamine in interstellar space, or as with the hydroxyl acids, the amines may share a common origin with the amino acids. By simply removing the carboxylic acid group of amino acids, 16 of the 20 amines can be made, a reaction that would take place if the molecules were heated on their parent asteroid.

Amides are structurally analogous to carboxylic acids and, in Murchison, the amide equivalents of monocarboxylic acids, dicarboxylic acids, and hydroxyacids are found in concentrations greater than 70 ppm (Cooper and Cronin, 1995). The amides display complete structural diversity up to and including molecules with eight carbon atoms, a decline in abundance with carbon number, and the presence of many compounds with no terrestrial source. Cyclic amides (lactams) are less abundant (2 ppm) but they are very interesting to

investigators of the origin of life. The chemical structures of cyclic amides permit hydrogen-bonded pair formation and may have acted as parts of a primitive genetic coding apparatus, possible forerunners of the present day nucleic acids.

Nitrogen heterocycles

Another compound class essential for terrestrial life is that of the nitrogen heterocycles. Some of these compounds are building blocks for nucleic acids that store genetic information. The possible presence of nitrogen heterocycles in water extracts of carbonaceous meteorites was first reported in the early 1960s but the initial optimism was dispelled when they turned out to be laboratory contaminants (Oró, 1963). Later work did confirm the presence of nitrogen heterocycles in meteorites such as Murchison and several classes, including purines, pyrimidines, quinolines/isoquinolines, and pyridines were found. All of the purines and pyrimidines found are biologically common and together account for 1.3 ppm in Murchison (Stoks and Schwartz, 1979, 1981). The quinolines, isoquinolines, and pyridines are structurally diverse, contain a large number of isomeric alkyl derivatives, and are present at concentrations of 7 ppm (Pizzarello et al., 2001; Stoks and Schwartz, 1982). Recent work has confirmed the presence and extraterrestrial origin of xanthine and uracil in the Murchison meteorite (Martins et al., 2008).

Sulfur heterocycles

Murchison contains small amounts of sulfur-containing compounds such as thiophenes, benzothiophenes, dibenzothiophenes, and benzonaphthothiophenes. The abundance pattern of thiophenes in Murchison is markedly different from those in terrestrial sediments, indicating an abiotic origin for these molecules (Shimoyama and Katsumata, 2001).

Phosphonic and sulfonic acids

Phosphorus compounds have many biological roles and play a part in cell membranes, energy transactions during metabolism, and the storage and transfer of genetic information. Sulfur compounds are also common in living systems and take part in key biochemical reactions. In Murchison, a series of alkyl phosphonic acids and alkyl sulfonic acids with up to four carbon atoms have been detected (Cooper et al., 1992). As observed for many of the other compound classes in Murchison, the sulfonic and phosphonic acids display an exponential decline in amount with increasing carbon number and exhibit complete structural diversity.

Macromolecular materials

The solvent soluble substances are only trace components, yet they are often the focus of studies on meteorite organic

matter due to their analytical amenability. Essentially, the macromolecular materials can be considered as a cross-linked agglomeration of some of the free compounds but with an overwhelming dominance of aromatic hydrocarbons. The macromolecular materials are generally assumed to be completely indigenous to their meteorite host due to their high molecular weight and immobility.

As the major organic component, the macromolecular material is key to theories of the origin of meteoritic organic matter as a whole. Hence it is interesting to consider that meteoritic organic matter is often compared with that observed in interstellar space. Some scientists believe that the molecular cloud that collapsed to form the solar system bequeathed a significant amount of interstellar organic matter, aliquots of which are preserved in primitive asteroids and the meteorites derived from them. For many years, only one- to four-ring polycyclic aromatic hydrocarbons (PAH) were commonly observed in Murchison macromolecular material breakdown products (Sephton et al., 1998), which contrasted sharply with the greater than 20-ring PAH proposed for the interstellar medium (Pendleton and Allamandola, 2002). Recently, using modern analytical techniques the meteoritic macromolecular material has yielded more information. Up to seven-ring PAH units have been liberated from the macromolecular material in Murchison and it appears that even larger entities are present in the experimental residue (Sephton et al., 2004). These discoveries partly reconcile the apparent disharmony between the meteoritic and interstellar organic inventories and point to a partly presolar origin for this abundant organic component.

Terrestrial contamination

Although some compound classes in meteorites may contain a record that extends back to interstellar environments before the solar system formed others can be much more recent in the form of terrestrial contamination. Unusual and subtle contamination sources exist and an example is provided by data from the Orgueil carbonaceous chondrite, which has a long curation history since its fall in 1864. Terpene-related compounds have been identified in this meteorite (Watson et al., 2003) and these compounds are structurally specific, and are unlikely to be produced by abiotic reactions. Terpenes are common in essential plant oils, used extensively in cleaning products, and may have percolated their way into the porous Orgueil stones.

A more widespread type of terrestrial contaminant is provided by the long-chain aliphatic hydrocarbons (normal alkanes) in meteorites (Sephton et al., 2001). Unlike the short-chain aliphatic hydrocarbons, the normal alkanes are structurally specific with all carbon atoms arranged in a straight chain. Normal alkanes in meteorites were first detected in Orgueil and were attributed to extraterrestrial biology based on similar distributions

for molecules in the meteorite and those found in butter and marine sediments (Nagy et al., 1961). Subsequent analyses on many different meteorites led to the discovery that these compounds were present in several tens of ppm, were concentrated near to the surfaces of samples, and that they were frequently associated with other, obviously terrestrial, compounds (Oró et al., 1966). A subsequent revival in the belief that these compounds were indigenous occurred when normal alkanes were interpreted as products of an abiotic catalytic reaction called the Fischer–Tropsch synthesis (Studier et al., 1968). Modern measurements of individual normal alkanes reveal terrestrial values that are distinct from the majority of meteoritic organic matter (Sephton et al., 2001) and imply that normal alkanes are simply contributions from our terrestrial environment once the meteorite has fallen on the Earth.

The location of organic matter in meteorites

In chondrites, organic matter is present within the fine-grained inorganic meteorite matrix, which contains evidence of alteration by liquid water on the parent asteroid. Hence, a general relationship between extraterrestrial organic matter and inorganic aqueous alteration products in carbonaceous chondrites has been recognized for some time. Recently, however, it has been discovered that the association is highly specific to a particular inorganic phase – clay minerals (Pearson et al., 2002). Clay minerals, therefore, may have trapped and concentrated organic matter in the early solar system and organic–inorganic interactions may have played a role in the assembly of increasingly complex organic entities 4.56×10^9 years ago.

Relevance to the origin of life on Earth

With the recognition that meteorites contain many biologically useful molecules it is enlightening to consider that the amounts of organic matter extraterrestrial objects can deliver to the Earth's surface are considerable. For example, calculations indicate that comet Halley contains organic matter equivalent to approximately 10% of the current biomass of the Earth (Greenberg, 1993). A connection between life and extraterrestrial material was first proposed in the early 1960s by the biochemist Jan Oró (Oró, 1961). It was suggested that extraterrestrial objects may have seeded the early Earth with an extensive list of ingredients for use in the recipe of life. Modern theories imply that the early Earth had a nonreducing atmosphere composed mainly of carbon dioxide and nitrogen in which the in situ generation of organic matter would be rather sluggish and inefficient. Even if only a small fraction of the molecules delivered by extraterrestrial infall proved biologically relevant, they would have had a significant impact on the prebiotic chemistry of the Earth.

Outlook

Until space missions begin to return large quantities of extraterrestrial material back to the Earth for analysis in laboratories, meteorites will remain the most accessible and most frequently studied objects to reveal the origin and evolution of the solar system. In particular, the study of carbonaceous meteorites, which contain bona fide prebiotic organic matter is likely to remain our most important means of determining how chemical evolution led to the origin of life.

METHANE OXIDATION (AEROBIC)

Helmut Bürgmann

Eawag, Swiss Federal Institute of Aquatic Science and Technology, Kastanienbaum, Switzerland

Synonyms

Methanotrophy

Definition

Methane oxidation is a microbial metabolic process for energy generation and carbon assimilation from methane that is carried out by specific groups of bacteria, the methanotrophs. Methane (CH_4) is oxidized with molecular oxygen (O_2) to carbon dioxide (CO_2).

Biochemical basis

Methanotrophy is the microbially mediated process of the oxidation of CH_4 with O_2 to methanol, formaldehyde, formate, and finally CO_2 (Figure 1) (Hanson and Hanson, 1996; Madigan et al., 2003; Bowman, 2006). The process is performed by a specialized group of bacteria (qv), the methanotrophs (CH_4 oxidizing bacteria). They are a subgroup of the methylotrophs, bacteria capable of utilizing single-carbon compounds (Bowman, 2006).

Methane is both the energy source (electron donor) and the sole or partial carbon source for methanotrophs. Aerobic oxidation of methane requires specific enzymes, most importantly methane monooxygenase (MMO), which catalyzes the first step in the reaction: the oxidation of methane with molecular oxygen to methanol and water. Two forms of this enzyme are known: particulate methane monooxygenase (pMMO), which is ubiquitous in methanotrophs and contains copper, and the iron-containing soluble methane monooxygenase (sMMO) (Hanson and Hanson, 1996). The reaction mediated by MMO requires additional electrons, which are supplied by cellular redox carriers such as cytochrome C (for pMMO) or NADH (sMMO). Energy is conserved in the subsequent stepwise oxidations of methanol, formaldehyde, and formate. In these reactions, electrons are donated back to a membrane-bound electron transport chain (see Chapter *Aerobic Metabolism*) via a pyrroloquinoline quinone cofactor to cytochrome C (methanol dehydrogenase) or NAD (in formaldehyde oxidation systems and formate dehydrogenase). Electron flow through the membrane ultimately produces a proton motive force that is converted to the cellular energy carrier ATP by the ATPase enzyme complex. O_2 is the terminal electron acceptor (see Chapter *Aerobic Metabolism*) (Figure 1) (Madigan et al., 2003). Thus, aerobic methane oxidation can be considered a special case of aerobic

Methane Oxidation (Aerobic), Figure 1 Pathway of aerobic methane oxidation for energy conservation and carbon assimilation in Type I and II methanotrophs. pMMO, particulate methane monooxygenase; MDH, methanol dehydrogenase; FAox, formaldehyde oxidation system (tetrahydrofolate- or methanopterin-dependent) FDH, formate dehydrogenase. Methane is oxidized with oxygen by pMMO, a step which requires reducing equivalents (e.g., from NADH) supplied by later oxidations in the pathway. Energy is generated by shuttling electrons generated in the subsequent oxidations of methanol (CH_3OH), formaldehyde (CH_2O), and formate (HCOO^-) through a membrane-bound electron transport chain that creates a proton gradient across the cell membrane (proton motive force) that can be converted into ATP by ATPase (oxidative phosphorylation). Formaldehyde (CH_2O) is the starting point for carbon assimilation via the ribulose monophosphate or serine pathways.

respiration. Differences between methanotrophs are thought to exist regarding the enzymes used, especially with regard to formaldehyde oxidation, where different systems are known (Lidstrom, 2006).

Methanotrophs

Most known methanotrophs fall into two well-defined phylogenetic groups belonging to the gamma- (Type I methanotrophs) and alpha-proteobacteria (Type II) that are also distinguished by morphological traits and differences in carbon assimilation (Hanson and Hanson, 1996; Madigan et al., 2003; Bowman, 2006). Both types share the characteristic extensive intracytoplasmic membrane system (ICM), which is the site of methane oxidation. However, in Type I methanotrophs, the ICM occurs as disk-shaped membrane stacks within the cell, while in Type II methanotrophs, the ICM is located around the periphery of the cell. Both groups are strict aerobes and obligate methylotrophs. The presence of soluble methane monooxygenase (sMMO) seems to be mostly limited to Type II methanotrophs (Hanson and Hanson, 1996; Bowman, 2006). Type I and II methanotrophs employ different carbon assimilation strategies, although both incorporate methane carbon at the level of formaldehyde (Figure 1). Type I methanotrophs use the ribulose monophosphate pathway and obtain all their carbon from methane. Type II methanotrophs use the serine pathway, which in addition to formaldehyde incorporation further involves fixation of one molecule of CO₂ per molecule of formaldehyde assimilated. The former pathway is energetically more favorable, requiring only 1/3 ATP per molecule formaldehyde fixed, instead of 1 ATP and reducing power for the serine pathway. This is in accordance with the observed higher growth rates in Type I methanotrophs (Madigan et al., 2003). Most methanotrophs can also grow using other single-carbon compounds, e.g., methanol, which is the first intermediate of methane oxidation.

Within the Type I methanotrophs, the genera *Methylosphaera*, *Methylobacter*, *Methyломicrobium*, *Methylomonas*, *Methylococcus*, and *Methylocaldum* have been described. The latter two genera are often distinguished as “type X methanotrophs,” as they are phylogenetically and morphologically distinct from the other Type I genera. The cultivated type II methanotrophs belong to the genera *Methylosinus* and *Methylocystis* (Bowman, 2006). Environmental clone libraries suggest the existence of additional, yet uncultured, genera. Recently, acidophilic methanotrophs belonging to the *Verrucomicrobia* phylum have been isolated, showing for the first time that not all methanotrophs belong to the proteobacteria and that methanotrophs are phylogenetically more diverse than previously thought (Dunfield et al., 2007; Pol et al., 2007). The genome sequence of one isolate revealed the presence of pMMO genes (pmoA), but lacked homologs to known methanol

monooxygenases and formaldehyde oxidation genes, indicating a methane oxidation system that deviates from those known from Type I and II methanotrophs (Dunfield et al., 2007).

Habitats

Although current isolates require high methane partial pressures for growth, some methanotrophs can apparently utilize methane with high affinity at low partial pressures, down to atmospheric levels (Hanson and Hanson, 1996). Therefore, they are ubiquitous in soil and water. Increased populations and activity occur wherever increased methane concentrations, whether from biogenic or other sources, meet oxic conditions. Typical habitats are thus closely tied to sites with methanogenesis (see Chapters *Methane, Origin*; *Methanogens*), e.g., rice paddies, swamps, aquatic and terrestrial sediments, land-fill coverings, and the oxycline of stratified water bodies (Hanson and Hanson, 1996). In stratified systems, (e.g., in stratified water bodies or sediments) aerobic methane oxidation will often be located within a relatively narrow band within the oxycline, where methanotrophs can become highly enriched. Methanotrophs also occur as endosymbionts, e.g., of marine mussels found at cold seeps (qv) that use methane released to supply their hosts with carbon and energy (Hanson and Hanson, 1996; Bowman, 2006).

Methods to study aerobic methane oxidation and methanotrophs

Methane oxidation rates in environmental samples are frequently determined by incubation experiments. Samples are placed in a gas-tight container and the consumption of methane over time is determined in the headspace. Alternatively, ¹⁴C labeled methane can be used to quantify the conversion to CO₂ and incorporation into the bacterial biomass. Field methods include the use of push–pull tests (Urmann et al., 2005), or modeling of rates based on methane gradients.

Methanotrophs can be cultured from almost any environment using a nitrate mineral salts medium and a CH₄/air atmosphere (Madigan et al., 2003; Bowman, 2006). Since they are relatively easily cultured, viable count methods can be used but will severely underestimate the actual population, due to the prevalence of viable but nonculturable cells. Since they are phylogenetically well defined, methanotrophs can be detected and quantified using ribosomal RNA as a genetic marker, e.g., using specific oligonucleotide probes (e.g., for fluorescent in-situ hybridization) or primers for polymerase chain reaction based detection (PCR) (McDonald et al., 2008). In addition, the gene sequences of functional genes, most frequently the gene encoding pMMO (pmoA), but also genes for sMMO (mmoX) and methanol dehydrogenase (mxaF), are frequently used as molecular markers for

PCR-based detection (Hanson and Hanson, 1996; Bowman, 2006; McDonald et al., 2008). A hybridization microarray was developed for rapid phylogenetic typing of PCR amplified *pmoA* (Bodrossy et al., 2003). Type I and II methanotrophs also contain biomarkers (see Chapter *Biomarkers (Organic, Compound-Specific Isotopes)*), e.g., specific lipids and phospholipid fatty acids that are useful in tracing community changes (Hanson and Hanson, 1996; Bowman, 2006; Schubert et al., 2006; Blumenberg et al., 2007).

Geochemical impact

Locally, methanotrophs can be an important basis of the food web, if sufficiently large fluxes of methane are converted to biomass and passed on down the food chain. Since biogenic methane (see Chapters *Methane, Origin; Methanogens*) has a strongly ^{13}C depleted carbon isotope signature, carbon flow originating from oxidized methane can be studied using isotope measurements (see Chapter *Isotopes (Methods)*).

The primary importance of aerobic methane oxidation for the global *carbon cycle* (qv) is that it represents (together with *anaerobic methane oxidation* (qv) and photochemical methane oxidation in the atmosphere) a major sink for this radiatively active and therefore, important greenhouse gas. Globally, photochemical methane oxidation is by far the dominant process (94%), but microbial oxidation is an important factor to take into account when projecting global warming effects. Obtaining global estimates of microbial aerobic methane oxidation is not trivial due to high spatial and temporal variability and the difficulty in performing rate measurements in environments where methanogenesis and methanotrophy occur simultaneously. The total sink function of soils has been estimated at 29 Tg year^{-1} , with an uncertainty range of 7–100 Tg year^{-1} (Smith et al., 2000). In rice paddies, methane oxidation can occur in the rhizosphere and at the soil surface, and is estimated to remove 80% of the methane produced in these systems, but there is uncertainty that CH_4 bypass would possibly occur through vascular plants' parenchyma. Methane oxidation rates in soil depend on various factors, e.g., soil bulk density, water content, temperature, and pH (Hanson and Hanson, 1996). The process is also often limited by the rate of methane diffusion into the oxic zone. Further, ammonium is a competing substrate for MMO that is not coupled to energy generation and therefore acts as a poison to methanotrophs at higher concentrations (Madigan et al., 2003). Thus, the methanotroph activity in soil is subject to considerable variability and sensitive to land use changes, and is one factor to be considered for mitigation strategies to reduce atmospheric methane concentrations (Hanson and Hanson, 1996).

Lakes were long considered a minor source of methane, a view that has somewhat changed based on observation of significant methane fluxes from reservoirs (St. Louis

et al., 2000). In permanently or temporally stratified water bodies such as lakes, reservoirs, or the Black Sea, a large proportion of the methane is oxidized by aerobic methanotrophs in the chemocline (Schubert et al., 2006; Blumenberg et al., 2007).

While the open ocean is not considered a major source of methane, and methane oxidation activity is generally low, *cold seeps* (qv) release large amounts of methane from sediments and hydrocarbon deposits (including *gas hydrates* (qv)), creating high local fluxes of methane (see Chapter *Methane, Origin*). This creates a situation where symbiotic as well as free-living methane oxidizers are the basis of large oceanic food webs. However, in anoxic marine sediments *anaerobic methane oxidation* (qv) coupled to sulfate reduction is the most important process.

Summary

Aerobic oxidation of methane is performed by specific bacteria, the methanotrophs, which use a specific metabolic pathway for carbon assimilation and energy generation from methane. Most known methanotrophs belong to the Proteobacteria, but recent discoveries of novel methanotroph *Verrucomicrobia* indicated that the diversity of methanotrophs is not yet fully known. Aerobic methane oxidation is one of the major sinks for the greenhouse gas methane, along with *anaerobic methane oxidation* (qv) and photochemical oxidation in the atmosphere. It is, thus, an important process for the global *carbon cycle* (qv) and an important element in the regulation of the atmospheric concentration of methane.

Definition

Methane is a colorless and odorless gas, with the chemical formula CH₄. Due to its radiative force, it is a strong greenhouse gas and contributes to the warming of the earth. It is formed in the environment by methanogenesis. The main natural sources are wetlands and termites (30% of total emissions), while anthropogenic sources include rice fields, cattle farming, and energy production (70% of total emissions).

General aspects

Methane is a colorless and odorless gas and the major component (97% vol.) of natural gas. Methane has a boiling point of −161°C at a pressure of one atmosphere. As a gas, it is flammable only over a narrow range of concentrations (5–15%) in air. It is mainly produced by microorganisms (methanogens) under anoxic conditions in a process called methanogenesis. These conditions exist under water-covered soils, such as rice paddies, tundra, swamps, and marshes, but also in freshwater and marine sediments. Other anoxic environments include ruminant stomachs and termite guts (see [Table 1](#)).

Methanogenesis is the final step in the anaerobic degradation of organic carbon, with methane being formed as a waste product. Methanogenesis is performed by strict anaerobes called methanogens, organisms belonging to the Archaea (a domain of life alongside Bacteria and Eukaryota). Methanogens are rather cosmopolitan in respect to environmental conditions (i.e., temperature, pH, salinity; as long as the environment is anoxic) and represent the largest and most diverse group in the Archaea domain (Magonigal et al., 2004; c.f. Boone et al., 1993). Methanogens are able to grow at temperatures between 4°C and 100°C, at pH values from 3 to 9, and at salinities ranging from brines to freshwater. Despite this huge taxonomic diversity, the substrates that can be used by methanogens are rather limited – hydrogen, acetate, formate, some alcohols, and methylated compounds (Zinder, 1993). The most important of these are hydrogen and acetate, which give rise to two different kinds of methanogenesis: (1) the fermentation of acetate to CO₂ and CH₄ and (2) the reduction of CO₂ with H₂.

Garcia et al. (2000) showed that over 70% of methanogens use the latter pathway, which is known as hydrogenotrophic methanogenesis or carbon dioxide/hydrogen reduction. Hydrogen in this reaction is used both as an energy source and electron donor, whereas CO₂ is the electron acceptor and the carbon source. This reaction yields the most energy of all methanogenic processes – much more than acetate fermentation, which yields the least (see [Table 2](#)). Since hydrogen occurs only in very low concentrations in natural environments, it is the limiting substrate in CO₂/H₂ reduction.

Only 10% of the methanogenic genera, i.e., *Methanosarcina* and *Methanosaeta*, are able to use the other pathway, called acetate fermentation or acetoclastic

MICROBIAL BIOMINERALIZATION

Christine Heim
 University of Göttingen, Göttingen, Germany

Synonyms

Microbial biomineral formation

Definition

Microbial biomineralization describes the formation and deposition of minerals directly mediated or indirectly influenced by microorganisms (Mann, 2001; Weiner and Dove, 2003; Ehrlich, 1999). A huge variety of minerals results from individual biomineralization pathways linked to the phylogeny and metabolic activity of the microorganisms involved (Weiner and Dove, 2003;

MICROBIAL DEGRADATION

Mineralization; Nutrient cycling

Definition

Microbial. Processes driven by microorganisms.

Degradation. Use of chemical substances as carbon and energy source for metabolism, thereby breaking down larger molecules to smaller ones.

Introduction

Microorganisms are the basis for the process of mineralization by utilizing organic molecules for their catabolism, thereby returning the elements to the geobiological cycles. In catabolism, or energy conservation, energy-rich adenosine triphosphate (ATP) is formed (for general reading on microbial physiology: Madigan and Martinko, 2006). This is the basis for metabolic degradation performed by microorganisms in a great diversity. The degradation of organic material in terrestrial, limnological, and marine environments is thus based on the growth of microorganisms on organic compounds, which is termed chemoheterotrophic growth style, depending on the availability of organic nutrients for growth. The processes can be dependent on aerobic respiration, but many degradative processes, e.g., in sediments, are performed in the absence of oxygen under anaerobic conditions (Schink, 2002).

Aerobic and anaerobic respiration

The respiration with oxygen as the terminal electron acceptor is the process yielding the most ATP per mol substance oxidized and thus, aerobic respiration is the preferred route for degradation whenever enough oxygen is available. Under aerobic conditions, the degradation of organic matter is performed following general and ubiquitous pathways such as glycolysis; the pyruvate produced in the glycolytic chain enters the citrate cycle; and the reduction equivalents produced are then reoxidized by the respiratory chain coupled to the reduction of oxygen to water. All building blocks of living cells can be degraded that way, allowing growth of microorganisms. The carbon moieties are released as CO₂ into the atmosphere.

Under anaerobic conditions, anaerobic respiratory chains using alternative electron acceptors can ensue. For example, nitrate, nitrite, sulfate, sulfite, sulfur, iron, manganese or fumarate, or carbon dioxide in methanogenesis is then used to accept the electrons, thereby reducing these substances. Halogenated compounds can serve as electron acceptors in dehalorespiration.

All these respiratory chains depend on membrane-bound electron transport, and the reactions of electron transport are coupled to proton export across the cellular membrane to form a proton motive force. The proton motive force is then used to drive ATP formation *via* the enzyme ATP synthase, which can form 1 mol of ATP per 3 mol of protons carried back into the cytoplasm. The electrons for electron transport chains are derived from oxidation of the organic molecules of the nutrient source. If possible, the organic matter is fully oxidized to carbon dioxide. In this way, the organic matter is fully decomposed.

Fermentation

Another route, independent of respiratory chains, is possible for the fermentative degradation of organic matter. The fermentations performed by microorganisms can use oxidation of substrates to produce ATP and then reduce organic molecules for reoxidation of the reducing equivalents. While ATP yield in these systems is limited when compared to respiration, it still allows growth under conditions when no inorganic electron acceptor is available in sufficient amounts, or when iron as part of the electron carriers in the respiratory chain is not available and therefore, an electron transport chain cannot be synthesized.

In contrast to respiration, both aerobic and anaerobic, during fermentation the organic substrate is not fully oxidized to CO₂. Rather, energy conservation is dependent on the oxidation of an organic molecule in which an aldehyde may be formed as intermediate, which subsequently can be oxidized to form an acid. This exergonic reaction is coupled to the activation of an inorganic phosphate moiety which then can be transferred to ADP, thereby forming ATP. This process is called substrate-level phosphorylation in contrast to the electron transport phosphorylation occurring in respiratory chains. The oxidative reaction releases reduction equivalents, which cannot be transferred to an inorganic electron acceptor due to the lack of respiratory chains in fermenting microbes. Thus, the reduction of an organic compound is necessary to release the carrier for a new cycle of oxidation. The reduced organic substance is released into the environment. An alternative is to release the reduction equivalents as H₂.

The fermentation of sugars, which are present in large amounts due to photosynthesis products and constituents of plant cell wall material, can be performed using the Embden–Meyerhof pathway of glycolysis, the Entner–Doudoroff pathway, or modifications or parts thereof. Sugars with 5 C moieties, sugar acids, or carbonic acids can be converted by different pathways. Examples for sugar fermentation are homo- or hetero-fermentative lactic acid fermentation, alcoholic fermentation, propionate fermentation, butyrate or butanole fermentation, mixed acid fermentation, solvent fermentation, and many others. The names of the pathways indicate the products released in these different fermentative pathways.

Many bacteria can switch between fermentative and respiratory metabolism, depending on the availability of

electron acceptors for respiratory chains. If they can switch between anaerobic and aerobic metabolism, they are called facultative aerobes, while anaerobes are usually oxygen sensitive and grow exclusively under anaerobic conditions. Within this group, the Gram-positive *Clostridia* have evolved many fermentation pathways including those to degrade fatty acids, lipids, amino acids and proteins, or nucleic acids under anaerobic conditions. Thus, degradation of all constituents of the cytosol of living organisms under anaerobic conditions can be achieved.

As no oxygen is necessary for the fermentative metabolism, most fermentations will proceed under anoxic conditions. However, aerotolerant microorganisms such as some lactic acid bacteria that are active in decomposition of plant litter can perform this reaction also under oxic conditions, although these anaerobes do not use oxygen as electron acceptor.

Syntrophic degradation

The reduced compounds released by fermenting microorganisms constitute good nutritional sources for organisms that can use respiratory systems. In turn, the use of the product will allow for the continuous production of this compound, as no restrictions for the fermenting bacteria will inhibit their metabolism. The concomitant occurrence of bacteria in an ecological niche in which both partners are dependent on each other and degradation of the substrate is only possible when both partners are present is termed syntrophy.

The basis is the metabolic activity of one organism which forms a substrate for the other. This constant removal of a metabolic end product is exemplified by the release of H_2 which is often a link in such syntrophic systems. Use of hydrogen by a second organism allows the first organism to constantly produce this compound. In pure culture, the partial pressure of H_2 reaches levels inhibitory to the metabolism of the producing organism which subsequently ceases growth. Since the syntrophic partner constantly removes hydrogen, no cessation of growth is observed due to product inhibition in this coculture. This syntrophy, depending on hydrogen transfer between two microbes present in the same environment, is of special importance, and the term interspecies hydrogen transfer has been coined for this syntrophic relationship. However, many different examples can be given for such syntrophic associations of microorganisms (e.g., Ueda and Beppu, 2007). Degradation of recalcitrant substrates, including, e.g., halogenated compounds, is often seen in syntrophic associations.

Cometabolic degradation

Recalcitrant substrates are not, or very slowly, degraded because their conversion is not easily or not at all coupled with energy conservation. Thus, the degradation of these compounds is costly for the cell, and the microorganisms do not profit directly from degradation. Instead, the

bacteria have to use energy from a different, catabolic reaction to drive the unfavorable degradation process.

An example of immediate importance is lignin degradation, which is performed by white rot fungi. The brown rot fungi degrade lignin mainly in order to get access to the cellulose of plant cell wall which is a good nutrient source but not directly accessible in wood and timber. The recalcitrant nature of lignin is seen under anoxic conditions, where the degradation is not possible and lignin of plant origin is thus the basis for coal formation.

As cometabolic systems are costly, they are mostly linked to respiration. Degradation of plant alkaloids, which are also recalcitrant substrates, often occurs at higher rates in oxic conditions.

Degradation of plant litter and soil formation

Plant material is composed of the contents of the living cells and the cell wall materials. Within the cell, secondary plant metabolites are stored in the vacuole. Upon leaf fall or death of a plant, especially the secondary metabolites and the wall materials persist, while proteins and lipids are easily degradable in the unsaturated oxygen containing upper soil layers.

Plant cell walls are composed of cellulose, hemicellulose, pectin, polygalacturonans, and lignin. Even in herbaceous plants, a quarter of the secondary cell wall is lignin. This macromolecule can be degraded aerobically, while anoxic conditions lead to the formation of coal, since under these conditions lignin cannot be degraded. Wood rotting fungi, both brown rot and white rot fungi, are able to degrade lignin (Crawford, 1981). The enzymes involved in lignin degradation, peroxidases and laccases, are able to attack the bonds in the macromolecule linking the phenolic monomers to form the high molecular weight lignin. The monomers can then be degraded further and are metabolized to carbon dioxide. These processes have been studied in some detail at the molecular level (Gold and Alic, 1993). Whether bacteria are also able to degrade wood is still under discussion. Streptomycetes are able to perform some partial degradation. However, complete decomposition has yet to be shown with bacterial systems.

An interesting question in wood and lignin degradation is regarding the possible symbiosis of wood degrading fungi and bacterial populations at an oxic/anoxic border. Anaerobic bacteria able to convert lignin decomposition products and partially degrade these compounds have been described. The fermentation products of these organisms may serve as growth substrates for the lignin degrading fungi. Secondary metabolites of plants and microorganisms are often recalcitrant because they contain aromatic rings, heterocycles, and polyketides or are halogenated. Such compounds are not easily degraded, especially under anoxic conditions. If degradation does not lead to complete oxidation of carbon moieties to CO_2 , the formation of humic acids and fulvic acids and thus the production of humus ensues. This process is the driving force for soil genesis. Under aerobic conditions,

enzymatic reactions known from lignin oxidation are often involved (Bumpus and Aust, 1987; Hammel, 1989).

Degradation of aromatic and halogenated compounds

Under aerobic conditions, the chemically very stable aromatic ring can be broken by activities of mono- and di-oxygenases. While monooxygenases introduce one of the oxygen atoms of molecular oxygen into the organic molecule forming a hydroxyl group at one site of the ring, dioxygenases incorporate both oxygen atoms which leads to decyclization and ring opening. The linear compound can then be further oxidized after activation and fueled into general metabolic pathways. The aerobic degradation of aromatic compounds can be used to clean oil spills or other anthropogenic contaminations, especially applicable for the residual contamination after a first mechanical cleansing has been performed. Inoculation of a beach after an oil spill could show visible removal of the remaining oil within 1 year.

Under anoxic conditions, the ring opening seems more difficult and it had long been argued that this would not be possible. However, bacterial enrichment cultures could show that an anaerobic degradation of aromatic compounds is possible usually via activation and conversion to benzoyl CoA followed by ring reduction. These energetically unfavorable reactions are feasible with a thermodynamically favorable electron acceptor, e.g., when nitrate is available in an anaerobic respiratory chain. Thus, bacteria related to the nitrogen fixing genus *Azoarcus* link the degradation of aromatic compounds with denitrification. Many gene clusters with different substrate specificities have been identified to perform anaerobic degradation of different organic molecules including aromatic amino acids, benzene and its derivatives, phenols, and heterocyclic compounds. The linearized structures again can be fueled into metabolic pathways via acetyl CoA or propionyl CoA. Anthropogenic aromatic compounds can be degraded by these same processes, thus allowing complete decomposition and natural attenuation. The introduction of bacteria able to anaerobically degrade aromatic compounds into aquifers with (anthropogenic) contaminations opens the road to bioremediation of contaminated groundwater resources. In tertiary oil recovery, introduction of bacteria into the well to partially degrade the high molecular crude oil fraction uses bacterial enzymatic activities to form molecules of lower molecular weight from the tar fraction that then can be recovered.

Many anthropogenic contaminations contain halogen atoms which generally decrease metabolic degradation of the compounds. However, halogenated compounds are also known from natural sources. These include antibiotics with chloride or bromide atoms, plant-derived alkyl halides, or deterrents incorporated into, e.g., marine slugs or tropical frogs. Since nature already has learned to cope with these halogenated compounds, anthropogenic

halogenated substances can also be degraded by bacterial consortia, both aerobically and anaerobically (Abraham et al., 2002; Smidt and de Vos, 2004). Not only bacteria are known to be able to perform dehalogenation reactions, but also basidiomycete fungi can also degrade organohalogens (de Jong and Field, 1997). While aerobic dehalogenation is a simple enzymatic reaction, anaerobic dehalorespiration is an interesting field of research. In this case, the dehalogenation is coupled with electron transfer and directly coupled to ATP formation in an anaerobic respiratory process.

Use of microbes in bioremediation

The properties discussed above make the use of microbia or microbial consortia useful for bioremediation of different contamination scenarios. These include aerobic conditions such as in soil, anoxic condition such as in aquifers or sediments, and all imaginable sources of contamination from oil spill to xenobiotics such as plant protection chemicals or heavy metals. Some recent reviews are included to facilitate further reading on microbial degradation (Holtze et al., 2008; Johnsen and Karlson, 2007; Demnerova et al., 2005; Pieper, 2005; Kim and Rhee, 2003) and bioremediation (Watanabe et al., 2002; R  ling and van Versefeld, 2002; Schwitzguebel et al., 2002).

Summary

The biogeochemical cycles of the macronutrients carbon, nitrogen, sulfur, and phosphorus are dependent on microbial degradation of organic matter. Organic matter originating from carbon dioxide fixation, which is in terrestrial system usually performed by photosynthetically active bacteria and plant, is degraded to form carbon dioxide, either directly in one metabolic reaction or by cocultures in which the intermediate is released and taken up by another microbe. In addition, the formation of methane from CO₂ or acetate is possible. Thus, the carbon cycling involves CO₂, CH₄, and organic molecules. Nitrogen fixation of N₂ to NH₃ followed by fixation in organic amines constitutes one side of the cycle, while nitrification/denitrification releases the bound nitrogen into the atmosphere. The latter reaction sequences, i.e., oxidation of NH₃ to NO₂[−] or NO₃[−] and nitrate or nitrite respiration leading to N₂ formation, are dominant processes in the cycling of nitrogen. For the sulfur cycle, assimilation of sulfates and fixation into organic biomass, the oxidation of sulfur and reduction of sulfate or sulfite to elemental sulfur, or reduction of sulfur to H₂S are the main processes. Sulfur is a constituent of the amino acids cysteine and methionine and of Fe/S clusters in redox enzymes. Phosphate is generally not altered; however, there have recently been reports on the use of phosphite in an unusual energy fixation process.

These elemental cycles in the biogeosphere all involve steps of fixation within living biomass, and the degradation of dead biomass is an essential part in releasing the mineralized elements back into the cycle. Higher

organisms are not capable of using plant litter, e.g., directly and thus entirely dependent on microbial degradation processes to have sufficient minerals available for their nutrition. Properties of microbes for degradation can be useful in bioremediation approaches.

MICROBIAL ECOLOGY OF SUBMARINE CAVES

Francesco Canganella, Giovanna Bianconi
 University of Tuscia, Viterbo, Italy

Definition

Essential concepts, current investigations, and discussion.

In recent years, the search for the limit of biodiversity in extreme and/or uncommon environments led to the investigation of peculiar ecosystems such as deep-sea, subterranean niches, Antarctic cores, hydrothermal vents, and extraterrestrial sites.

Submarine caves and cavities have also been explored, some were mainly exploited as popular attractions for scuba divers, but some were shown to be of great interest for geologists, biologists, and microbiologists.

Available scientific data on these ecosystems are not abundant, particularly as far as biological disciplines are concerned. Most of the published works have been related to specific submarine cavities known as Blue Holes and Black Holes, as well as to submarine caves showing inner sulfidic emissions. A larger number of data are currently available regarding the microbiology of terrestrial caves, particularly on the microbial ecology of carbonate layers, sediments, bat guano, and flooding waters (Vlasceanu et al., 1997, 2000; Holmes et al., 2001; Engel et al., 2003; Northup et al., 2003; Sugita et al., 2005; Zhou et al., 2007), but these latter ecosystems are not part of the current review.

Blue holes and black holes

The so-called blue holes are underwater karst systems which can develop horizontally in a very extensive way and appear blue due to a combination of blue sky reflection with the white carbonate sand deposited in the cave (Smart et al., 1988; Mylroie et al., 1995; Schwabe et al., 1997; Marano-Briggs, 2000; Colantoni et al., 2003; Canganella et al., 2004). Most of these sites were found and described in Bahamas and Hawaii.

Other cavern systems are known as “black holes,” which are cave systems without known lateral passages and located in the interior regions of the larger Bahamian islands. Most black holes are located in the central to western side of the island of South Andros in the Bahamas (Figure 1), although one has been found on the northern transitional shore of the Grand Bahama Island. They are vertical cave systems which

ANAEROBIC TRANSFORMATION PROCESSES, MICROBIOLOGY

Bernhard Schink

University of Konstanz, Konstanz, Germany

Definition and Introduction

Microbial activities in geochemical processes are most often redox reactions, either between organic matter and inorganic compounds or between different inorganic compounds. In surface soils and lake sediments, organic matter typically derives from primary production by land plants or aquatic plants including algae, provided either directly or after primary digestion by animals. Underground soils and groundwater may receive major amounts of comparably stable organic matter, most often petroleum and its derivatives, through spills and accidents. Microbial oxidation helps to eliminate such contaminants, with concomitant reduction of inorganic electron acceptors. The surprising abundance of bacteria-like structures and even living bacteria in Deep Sea sediments and terrestrial rock material down to several 100 m below surface raised the question of how microbial life can be fuelled in the apparent absence of perceptible external substrate input. The

present overview will try to provide access for geoscientists and other nonbiologists to the concepts of microbial life in the anaerobic world in general.

The terms “anoxic” and “anaerobic” are often used simultaneously with more or less the same meaning. Anoxic means “oxygen-free” and refers to habitats, incubation conditions, etc. The term anaerobic contains the Greek root “bios” (life) and refers to microbes, microbial activities, enzymes, etc.

Organic matter as electron donor in geochemical processes

Organic matter as supplied by plant primary production consists mainly of carbohydrates, proteins, fats, and nucleic acids. Digestion by soil animals decreases the carbohydrate and protein fraction, and increases the content of polyanellated phenolic residues (humic compounds, Stevenson, 1994). The complete oxidation of carbohydrates at pH 7.0, using glucose as a representative molecule, yields electrons at $E_0' = -434$ mV on average (Figure 1a). These electrons are transferred inside microbial cells via specific electron carrier systems, most often via NAD^+/NADH , at $E_0' = -320$ mV. Other carriers operate at lower (e.g., ferredoxins around -420 mV) or higher (flavins, quinones, cytochromes; Figure 1b) redox

Anaerobic Transformation Processes, Microbiology, Figure 1 Redox potentials of (a) organic substrates, (b) biochemical electron carriers, and (c) natural electron acceptor/donor systems. Values taken or calculated from Thauer et al. (1977) and Zehnder and Stumm (1988). MQ menaquinone; UQ ubiquinone.

potentials, and finally all electrons may end up at the O_2/H_2O -couple at $E_0' = +810$ mV (Figure 1c). Electron transport from low to high redox potentials provides chemical energy, which the cell conserves in energy-rich phosphoric acid anhydride linkages in the form of ATP which can be formed in the cell basically by two alternative processes (Thauer et al., 1977): In substrate-level phosphorylation, the transformation of a substrate molecule leads directly to an energy-rich intermediate from which ATP is formed in a stoichiometrically linked reaction. In electron transport phosphorylation, electron transport over a sufficient redox potential difference is coupled to the establishment of a proton (sometimes Na^+ ion) gradient across the cytoplasmic membrane which secondarily drives ATP synthesis via a membrane-bound ATP synthase reaction. Major steps in electron transport phosphorylation are the electron transports between NADH and the quinones, between quinones and cytochrome c, and between cytochrome c and oxygen (Figure 1b and c). In total, oxidation of glucose to $6CO_2$ with oxygen as electron acceptor can yield up to 38 mol ATP per mol glucose (Fuchs, 2006).

Partial digestion of biomass leads to less energy-rich derivatives that are less valuable as electron donors. Incomplete oxidation and polymerization of aromatic and aliphatic plant matter residues forms humic compounds with a comparably long residence time of up to 100 years in soils. An average redox potential of humic compounds can be calculated with hydroquinone as a representative constituent, yielding a value at -280 to -300 mV. Fermentation of sugars and proteins produces acetate as the most important primary product; its oxidation yields electrons at -290 mV on average. Oxidation of aliphatic and aromatic hydrocarbons releases electrons at -240 to -270 mV. These examples illustrate that the typical constituents of partly digested or stabilized organic matter are less valuable electron donors in oxidation processes. Moreover, especially humic compounds and hydrocarbons are already comparably inert derivatives. Efficient degradation of these compounds requires molecular oxygen as a co-substrate in the initial oxygenase reactions for activation. Since oxygen-independent alternative reactions of activation of hydrocarbons (Widdel et al., 1993) or polyanellated aromatic compounds (humic compounds) are slow compared to the known oxygen-dependent ones, a major amount of organic matter (e.g., peat) is conserved in the absence of oxygen ("latch hypothesis"; Freeman et al., 2001).

The biogeochemical redox chain

Due to the low solubility of oxygen in water (about $300 \mu M$ O_2 in freshwater at air saturation and $10^\circ C$), aerobic oxidation of organic matter depends on a continuous supply of oxygen, either by plant photosynthesis or by convective transport from the atmosphere. Therefore, this oxygen supply is restricted to only few millimeters below the top surface in sediments or soils where only diffusive transport is possible. Under such conditions, other

electron acceptors can substitute for oxygen in its function as an electron acceptor, and the sequence of these subsequent redox processes is determined by the standard redox potentials of the individual redox processes (Zehnder and Stumm, 1988; Figure 1c). After oxygen consumption, nitrate is reduced first to nitrite, and afterwards either to N_2 via NO and N_2O , or to ammonia. In any case, nitrite is an important intermediate which may accumulate in laboratory experiments to toxic concentrations. In nature, nitrate concentrations rarely exceed $50 \mu M$ and nitrite never becomes toxic, therefore. As the redox potentials listed in Figure 1 indicate, nitrate reduction to N_2 (denitrification) appears to be energetically more feasible than nitrate reduction to ammonia (nitrate ammonification). However, some redox steps in denitrification are rather inefficiently coupled to ATP synthesis, thus wasting a considerable amount of energy and rendering nitrate ammonification the more efficient way of nitrate-dependent energy conservation (Strohm et al., 2007).

Subsequently, manganese(IV) oxides, e.g., MnO_2 (Braunstein), may be reduced to Mn^{2+} ions. The distribution of manganese oxides in soils is rather patchy; in lake sediments, it depends primarily on the chemistry of the catchment area. In Lake Constance, the eastern part of the lake receives ample supply of manganese oxides through the Alpine Rhine river whereas the western part of the lake is nearly devoid of manganese. Different from manganese, iron is a very dominant constituent of rocks and sediments, and can make up up to 1% of the total dry mass. Iron oxides, similar to manganese oxides, are nearly insoluble at neutral pH, and the redox potentials of Fe(III)-oxide reduction to Fe^{2+} -ions depends even on the individual iron(III) mineral involved ($+100$ mV with ferrihydrite, -287 mV with hematite; Widdel et al., 1993; Straub et al., 2005). The main problem in reduction of iron and manganese oxides is their apparent insolubility (Cornell and Schwertmann, 1996) and, with this, the necessity for bacteria to transport electrons to an acceptor outside the cell (see below).

Reduction of sulfate to sulfide is the dominant process of organic matter oxidation in marine sediments because seawater contains sulfate at high concentration (28 mM). Freshwaters contain far less sulfate (50 – $200 \mu M$) rendering this process substantially less important at first sight. Nonetheless, sulfide can be reoxidized, e.g., with Fe(III)-oxides (see below) thus making reduction of sulfur compounds probably far more important in freshwater systems than assumed so far. The key problem in sulfate reduction is the initial reduction of the comparably stable sulfate molecule to sulfite which corresponds to a very low redox potential ($E_0' = -527$ mV) that cannot be fed directly with electrons from organic carbon oxidation. The sulfate reducers overcome this problem by ATP investment into this step, thus shifting the resulting redox potential to -60 mV (for details, see Cypionka, *Aerobic Metabolism*). The ATP required for this initial activation step is recovered in the further reduction of sulfite to sulfide.

Elemental sulfur is reduced by specific sulfur-reducing bacteria, but also by sulfate reducers. Elemental sulfur is easy to reduce and does not require prior activation. The problem of sulfur metabolism is again its low solubility in water which may be circumvented by the intermediate formation of water-soluble polysulfides in the presence of the formed hydrogen sulfide.

The terminal process in organic matter degradation in freshwater environments is the formation of methane, either by reduction of CO_2 or by cleavage of acetate (Wolfe, 1992; Thauer, 1998); alternatively, acetate may be formed first by CO_2 reduction, and secondarily be converted to methane (Drake et al., 2002; K. Kuesel, this series). Since the methanogenic archaeobacteria are restricted to the use of only very few substrates (H_2 , C_1 compounds, and acetate) complex organic matter has to go through fermentations by several groups of specialized bacteria (Schink, 1997) before it finally ends up in a mix of CH_4 and CO_2 , i.e., in complete dismutation of the carbon atoms.

Hydrogen is an important product of microbial fermentations of organic matter. It can be formed as well by geochemical processes and may be a source for microbial life in deep sediments and rocks.

The middle axis in Figure 1 (b) positions the key elements of the biochemical electron transport chain between organic matter on the left and the various acceptor systems on the right. This arrangement illustrates the major paths of electron flow in microbial transformation processes. One should emphasize, however, that biological systems are able to shift electrons also against the “normal” electron flow by “reversed electron transport” at the expense of energy supplied by transport of other electrons in the “normal” direction from negative to positive potentials. The scheme illustrates that glucose is comparably a valuable electron donor whereas the electrons derived in degradation of acetate, humic compounds, or hydrocarbons cannot all be transported via NADH, rather, many of them have to enter the transport chain at the level of quinones (either menaquinone or ubiquinone) with the consequence that substantially less ATP is formed. The scheme also illustrates that, e.g., reduction of ferrihydrite can be fed with electrons only at the potential of quinones, and that necessarily the ATP yield of this process is much smaller than, e.g., that of the reduction of nitrate or oxygen. It also becomes evident that phosphate can hardly be reduced to phosphine in a respiratory process, analogous to sulfate or nitrate reduction, but would require substantial amounts of energy rather than yield energy. The origin of traces of phosphine in certain anoxic environments is still unclear; it probably derives from corrosion of iron phosphides in scrap metals (Ding et al., 2005).

Lithotrophic reoxidations

The reduced derivatives formed in the processes above during oxidation of organic matter can act again as electron donors in microbial energy metabolism, e.g., if H_2S ,

reduced Fe^{2+} , or Mn^{2+} diffuses upwards and meets electron acceptors of higher redox potential, thus again creating a redox couple that can yield energy. Such metabolic activities are called “lithotrophic” (Greek *lithos* = rock) because in this metabolism inorganic electron donors serve as electron source. A lithotrophic metabolism is most often, but not necessarily, combined with autotrophic fixation of CO_2 into cell material, i.e., bacterial growth. Obviously, synthesis of organic matter from inorganic sources has to be fueled by energy (ATP) that is derived, in this case, from inorganic redox processes. Therefore, the yield of organic matter, i.e., of microbial cell mass, in these processes is usually small. As the redox chain in Figure 1c illustrates, H_2 , H_2S , and Fe^{2+} are good electron donors whereas nitrite, selenite, and Mn^{2+} are not. Behind every such redox process stand the activities of specialized bacteria and archaea which try to exploit every fraction of energy that can be derived from these redox processes.

An exceptional case is methane oxidation which can proceed either with oxygen as a co-substrate and an electron acceptor, yielding a huge amount of energy or with sulfate as electron acceptor (anaerobic methane oxidation; see Boetius, *Anaerobic Oxidation of Methane with Sulfate*) yielding extremely little energy. Similar problems apply to higher aliphatic or aromatic hydrocarbons (Spormann and Widdel, 2000).

Oxidation of sulfide with ferric oxides should yield energy as well. Nonetheless, this reaction proceeds spontaneously as a chemical reaction (see below), and so far there is no indication for microbial activity exploiting this redox reaction.

Energetics

Bacterial growth requires energy which is derived from substrate conversions in the form of ATP. Irreversible synthesis of the energy-rich acid anhydride linkage of ATP by condensation of ADP with a phosphoryl residue under the conditions prevailing in living cells requires energy (ΔG^0 or Gibbs free energy) in the range of 60–70 kJ per mol (Thauer et al., 1977; Schink, 1997). Nonetheless, metabolic energy can also be converted into ATP at smaller increments. The membrane-bound ATPase enzyme mentioned above catalyzes the synthesis of ATP reversibly with a translocation of protons or Na^+ -ions; the stoichiometry is 3–4 H^+ or Na^+ ions per ATP. Thus, any reaction that can be coupled to the translocation of protons or Na^+ -ions across the membrane can be associated with ATP synthesis, down to reactions transferring only 1 H^+/Na^+ , equivalent to an ΔG^0 in the range of 15–20 kJ per mol. Of course, reactions can proceed also with lower energy yields, but then they cannot feed ATP synthesis and bacterial growth. Growth, on the other hand, is a very important means to maintain a degradative capacity in a certain environment and to adjust its activity to the local needs (different from so-called “co-metabolic” activities which are not positively correlated with bacterial growth; McCarty, 1988).

Extracellular electron transfer

Electron transfer from or into the electron transport chain (Figure 1b) is easy with substrates that can be taken up into the bacterium in a dissolved form. Non-dissolved substrates have to be oxidized or reduced outside the cell, either at the immediate cell surface or via dissolved electron carriers. The reduction of ferric iron oxides can be accomplished in direct contact with the bacterial cells; perhaps, even small cellular appendages can act as “nanowires” for electron transfer (Reguera et al., 2005). Alternatively, either dissolved humic compounds (Lovley et al., 1996) or low-molecular weight quinoid or phenazine compounds may act as electron carriers (Hernandez et al., 2004). As a further alternative, sulfur-reducing bacteria can indirectly reduce iron via H_2S at low (<0.1 mM) concentration (Straub and Schink, 2004). At low H_2S concentration, H_2S delivers electrons to ferric oxides and is converted to a more oxidized species, perhaps thiosulfate or polysulfide, which is reduced again by the bacterium. In this case, a small sulfur cycle acts as an electron delivery system. One should emphasize that in the latter cases, the bacteria do not actually reduce the ferric oxide. They reduce quinoid or sulfur compounds, and the ferric oxides are reduced indirectly in a subsequent unspecific reaction. Such secondary electron transfer reactions may be important also with respect to other reductive transformations such as nitro group reduction, dehalogenation, etc. (Holliger et al., 1997).

The example of indirect ferric iron reduction via sulfur compounds appears to contradict the generally accepted preference of biochemical redox processes according to the sequence mentioned above: since the redox potential of the iron(III)/ Fe^{2+} -couple is higher than that of the sulfate/sulfide system, iron should be reduced before the sulfur compounds. Nonetheless, for bacteria not only the redox potentials but also the bioavailability aspect counts: since the sulfur compounds are easier to access they may be preferred over the insoluble iron oxides.

Phototrophic activities

Photosynthesis as performed by green plants and algae is called oxygenic because molecular oxygen is released from water through the activity of two combined light reactions. This biochemical potential was evolved by cyanobacteria (formerly called blue-green algae) and the evolution of oxygenic photosynthesis has changed the chemistry of our planet around 3.5 billion years ago in a most dramatic way from a reducing to an oxygenated atmosphere. The massive precipitation of iron oxides in the so-called “Banded Iron Formations” has for long times been considered to witness the evolution of molecular oxygen in the Earth’s atmosphere, but the oxygen thus evolved would have been consumed to a large extent over several hundred million years in the oxidation of Fe^{2+} to ferric oxides. Anoxygenic phototrophic bacteria perform a simpler, older type of photosynthesis from which oxygenic photosynthesis was later derived. The discovery of

Fe^{2+} -oxidation by anoxygenic phototrophs (Widdel et al., 1993) changed also our understanding of the development of Banded Iron Formations; this process became possible also without the involvement of molecular oxygen, and thus formation of Banded Iron Formations could now testify only the evolution of anoxygenic, rather than of oxygenic photosynthesis (Kappler et al., 2005).

Spatial/seasonal oscillations

Many microbial habitats such as the Deep Sea and its sediments, or rocks in the deep underground are highly stable systems which do not change their properties over many thousands or millions of years. On the other hand, microbial life conditions in a top soil may change dramatically with every rainfall, and bacteria inhabiting the sediment surface in a shallow, light-exposed lake may undergo dramatic life changes in diurnal cycles of light and oxygen supply which are probably the most dramatic changes for living systems at all. As shown in Figure 2, oxygen profiles during light exposure versus darkness show dramatic differences with respect to the oxygen concentration and to oxygen penetration depth into the sediment. Other parameters change over longer time scales, e.g., with seasons. Figure 3 shows a section of the littoral sediment of Lake Constance in January when the water level is low.

Anaerobic Transformation Processes, Microbiology, Figure 2 Distribution profiles of oxygen in littoral sediment of Lake Constance under the influence of different light conditions. (x) 12 h dark, (+) 12 h incubation at low light, equivalent to an overcast day, (*) 12 h incubation at high light intensity, equivalent to a sunny day. Incubation basins were exposed to light under a 12 h-light-dark cycle with three Osram lamps Biolux (L30W/72), Fluora (L30W/77), and Haloline (200 W/R7s) to generate high light intensity of 15 kLux ($250 \text{ E m}^{-2} \text{ s}^{-1}$) at the water surface.

Anaerobic Transformation Processes, Microbiology,

Figure 3 Leaching of ferrous iron from littoral sediment of Lake Constance in Winter 2002. Fe^{2+} ions leach from the upper right part to the left, with continuous chemical/microbial oxidation of Fe(II) to Fe(III) oxides.

The higher regions of the sediment (which are under water through the major part of the year, with annual water level changes of 2.5 m) are exposed to air in wintertime, and the reduced Fe^{2+} leaches out of the sediment to be oxidized to Fe(III) oxides. Of course, such water level fluctuations influence all life forms in the littoral sediment, beyond the normal fluctuations of light and dark in the day cycle, and of temperature through the annual cycle. The microbial community within the sediment either has to adapt to these changes as far as possible or has to migrate within the sediment to maintain a stable life situation.

Conclusions

Microbes are magnificent chemists. They catalyze reactions that are thermodynamically feasible, but enhance them kinetically as any good catalyst does. Beyond that, they can couple exergonic reactions in their energy metabolism with endergonic processes in their assimilatory metabolism in a way that chemical processes could never accomplish. Through bacterial growth, the catalytic potential is adjusted at a certain site to the local needs. Many processes are strongly accelerated by the action of microbes, and the total extent of their activities in Deep Sea sediments and in the deep underground can so far only roughly be estimated. Nonetheless, there is little doubt that microbes in the underground make up a significant part of living protoplasm on Earth in general, ranging in the same order of magnitude as that of plants and animals together (Whitman et al., 1998). The fascinating efficiency with which microbes catalyze chemical processes into impressive dimensions (as, e.g., in the precipitation of the Banded Iron Formations) gives us only a vague idea of the importance of microbial catalysis in the geochemistry of our planet. Geochemists and geomicrobiologists have to join their forces to understand the action of microbes in highly structured environments that appear extremely

poor with respect to utilizable energy sources, in order to assess the contributions of life to geochemistry correctly.

Introduction

One of the major events in the evolution of multicellular animals was the transition from soft-bodied organisms to those that possessed mineralized hard parts for protection

and support. This major evolutionary hallmark supported the rapid diversification of animals and their occupation of a diverse range of novel ecological niches at the dawn of the Phanerozoic, between 560 and 530 million years ago, when mineralized skeletons appeared relatively synchronous in a variety of Phyla during the so-called Cambrian Explosion (Knoll, 2003; Conway Morris, 2006). However, it is still unclear exactly what drove this sudden capacity to construct mineralized structures, be it changes in ocean chemistry (Brennan et al., 2004) or the evolution of more diverse ecologies (Cohen, 2005), including predators (Vermeij, 1989). Investigation of biomineralization processes will provide insight into the molecular and genetic mechanisms that accompanied the appearance of mineralized body parts during the early Cambrian, shedding light on the processes that generate the diversity of life we see around us today.

Until recently, studies of biomineralization processes were mainly restricted to describing the (ultra)structure of the minerals and their interaction with the organic material provided by the organism (Lowenstam and Weiner, 1989; Mann and Webb, 1989). However, the generation and elaboration of biominerals is ultimately controlled by genes (Jackson et al., 2006, 2007a, b), which must in turn be expressed in the appropriate tissue and at an appropriate stage of development. Understanding the evolution of such biomineralizing genes and the gene regulatory networks (GRNs) in which they act is, therefore, vital to the understanding of how animals evolved and will also provide clues for the fabrication of biomimetic materials.

Biomineralization

Biomineralization refers to the processes by which organisms form minerals (e.g., calcium carbonate, calcium phosphate, silica, iron oxides) under strict biological control. These processes are, therefore, defined as *biologically controlled mineralization*, with the skeletons formed being integral, functional parts of the organisms (Lowenstam and Weiner, 1989). There are, however, several other serendipitous processes linked to living organisms (e.g., microbes) or organic substances that result in mineral (mainly calcium carbonate) formation that are not under strict control of organisms. These processes are termed either *biologically induced mineralization*, where inorganic minerals are precipitated by adventitious precipitation resulting from secondary interactions between various metabolic processes and the surrounding environment (Mann, 2001), or *organomineralization*, a term used to describe mineralization processes that involve organic molecules or particles, whether linked to living organisms or not (e.g., degrading organic matter) (Trichet and Defarge, 1995).

While both *biologically induced* and *organomineralization* play an important role in the formation of carbonate systems in the geological record (e.g., microbialites, stromatolites, ooids) (Reitner and Neuweiler, 1995; Arp,

Definition

Microbial mats are often centimeter-thick multilayered structures of microorganisms, mainly bacteria, archaea, fungi, and sometimes these mats are enriched with protozoans. Microbial biofilms are in contrast much thinner (10–100 μm) than microbial mats and have a different architecture (Characklis and Wilderer, 1989). Microbial mats grow at interfaces between different types of material, mostly on moist surfaces, but some of them are also found in dry environments like deserts (e.g., Stal and Caumette, 1994; Characklis and Wilderer, 1989). They colonize environments located in high altitude, they are common in the Deep Biosphere, in subterranean environments with temperatures from -40°C to $+120^{\circ}\text{C}$. There are also common as endosymbiotic structures, for example, in animals. They are very common in extreme environments like hydrothermal vents, cold seeps, and alkaline and hypersaline lakes (Van Dover, 2000; Pederesen, 2006; Arp et al., 2003; Riding and Awramik, 2000).

Geobiological implications

A microbial mat consists of several layers dominated by specific types of microorganism (Figures 1 and 2). Although the composition of individual mats varies depending on the environment, as a rule the by-products of each group of microorganisms serve as energy source for other groups. Different types of microorganisms dominate different layers based on their comparative advantage (Canfield and Des Marais, 1993; Allison et al., 2000). Ecological relationships between different groups are a combination of competition and cooperation. The metabolic capabilities of bacteria and archaea are generally depend on their phylogeny. In a wet environment where sunlight is available, the upper layers are generally dominated by aerobic consortia like cyanobacteria (Figure 1), while the lowest layers are normally dominated by anaerobic microorganisms such as sulfate-reducing bacteria, methanogenic and/or methanotrophic archaea, or general archaea. Marine mats may grow to a few centimeters in thickness, of which only the top few millimeters are oxygenated. Microbial mats are held together and bound to their substrates by sugar- and protein-rich extracellular polymeric substances (EPS), which they secrete (Decho et al., 2005; Wingender et al., 1999). In many cases, some of these microorganisms form filaments (threads), which tangle and thus increase the microbial

The entire mat is interspersed with authigenic, spherulitic aragonite, and gypsum crystals that are growing within EPS.

colonies structural strength, especially if the filaments have sheaths.

Microbial mats are the earliest complex form of life on Earth. There is a fossil record from 3,500 million years ago, and they have always been the most important members and maintainers of earth ecosystems (Allwood et al., 2006; van Kranendonk, 2007). Early Precambrian microbial mats are the first evolved highly complexly organized multicellular organisms. Microbial mats occasionally mineralize if the ionic strength in the aquatic environment allows it. The mineralized structures are known as stromatolites and thrombolites and they represent the most important organo-sedimentary fabrics since the early beginning of microbial life on earth (Burne and Moore, 1987; Riding, 2000). Originally, microbial mats first occurred at hydrothermal vents for energy. Since the late Precambrian microbial mats have also played an important role at cold hydrocarbon seeps, so-called Cold Seeps. Most of the Cold Seeps are methane vents coupled with hydrogen sulfur microbial metabolism (Reitner et al., 2005) (Figure 2). However, phototrophic microorganisms such as cyanobacteria, unicellular algae (e.g., diatoms), and related consortia are the most abundant microorganisms in the formation of microbial mats (e.g., Arp et al., 2010). Within subterranean environments iron-oxidizing microbial consortia show a strong ability to form thick microbial mats (Kurz et al., 2010).

Microbial mats are the context within which the first multicellular organisms evolved. Sponges are, for

Microbial Mats, Figure 2 Anaerobic microbial mat from a cold seep environment of the Black Sea. Black mat represents the outer margin of the microbial mat. This mat is dominated by ANME 2 archaea and greigite-bearing sulfate reducing bacteria (GHOSTDABS field, for details see Reitner et al., 2005; Reitner, 2010). Orange-pink mat represents an archaea-(ANME1)-dominated mat portion. The green mat represents the inner most area close to the methane vent. This mat is also dominated by ANME archaea, Crenarcheota, and anaerobic bacteria. The entire mat is stabilized by authigenic methane-related aragonite and calcite crystal aggregates, which are also growing within EPS.

example, highly evolved microbial mats with a mutual relationship with eukaryote choanoflagellates. May be the Vendobionta, large Ediacaran organisms with characteristic quilt bauplan are part of well-developed microbial mats and may themselves be large colonies of various microbial communities (Seilacher, 1999; Schieber et al., 2007; Steiner and Reitner, 2001).

Conclusion

Microbial mats are normally cm-thick microbial communities often related with microbially induced mineral precipitates (calcite, aragonite, iron-oxides etc.). Characteristic for these mats is a multilayered structure which represents various microbial communities with different metabolic activities. In phototrophic microbial mats (e.g., cyanobacteria) dominate the uppermost layers whereas within the deep layers of the mats anaerobic microbes dominate like sulphate reducing bacteria and archaea. Microbial mats are complex multicellular systems which exhibit some accordance to basic metazoans like sponges. It is speculated that microbial mats are a model for the basic metazoan bauplan.

MICROBIAL SILICIFICATION – BACTERIA (OR PASSIVE)

Kurt O. Konhauser, Brian Jones
 University of Alberta, Edmonton, Alberta, Canada

Definition

The encrustation, impregnation, and/or replacement of microbial tissue by silica minerals, usually opal-A.

Overview

Silica precipitation is an important geological process in many modern geothermal systems where venting of super-saturated solutions leads to the formation of finely laminated siliceous sinters around geyser and hot spring vents and on their discharge aprons. The spring waters, which typically originate from deep, hot reservoirs, at equilibrium with quartz, commonly contain dissolved silica concentrations significantly higher than the solubility of amorphous silica at 100°C (Fournier, 1985). Therefore, when these fluids are discharged at the surface, decompressional degassing, rapid cooling to ambient temperatures, evaporation, mixing, and changes in solution pH collectively cause the solution to suddenly become supersaturated with respect to amorphous silica (also known as opal-A). In such supersaturated solutions, the discharged monomeric silica, Si(OH)₄, polymerizes, initially to oligomers (e.g., dimers, trimers, and tetramers), and eventually to polymeric species with spherical diameters of 1–5 nm, as the silanol groups (–Si–OH–) of each oligomer condense and dehydrate to produce the siloxane (–Si–O–Si–) cores of larger polymers. The polymers grow in size through Ostwald ripening such that a bimodal

MICROBIAL-METAL BINDING

Kurt O. Konhauser, David A. Fowle
 University of Alberta, Edmonton, Alberta, Canada

Definition

The accumulation of metal cations to microbes, largely through adsorptive processes to the outer cellular surfaces.

Overview

All bacteria have low isoelectric points (below pH 2 in most cases), and consequently, they interact with soluble metal cations and have them intimately associated with their surfaces (Harden and Harris, 1953). Considering their ubiquity in the near-surface environment and their characteristically large surface area-to-volume ratios, bacteria can have a significant influence on metal mobility and speciation in these settings.

Some bound metals (e.g., Ca and Mg) serve the purpose of stabilizing the negative charges of the anionic functional groups, and thus are relatively “fixed” into place, while other metals are much more exchangeable and provide a temporary positive charge to counter the negative charge induced by the deprotonation of the cell’s surface functional groups (Carstensen and Marquis, 1968). The strength of the metal–microbial bond is quantified by the surface complexation/binding constant (K_M), where M refers to the specific metal of interest. The greater its surface complex formation constant, the less likely

a metal cation will be desorbed into solution. Metal cation sorption is also directly affected by pH, which dictates metal partitioning (or speciation) between solid and soluble phases, and hence, controls its mobility, reactivity, and toxicity in aquatic environments. Of particular importance here is the hydrolysis constant, which measures the tendency of proton release from the hydration sphere of the cation. Figure 1 depicts a generalized adsorption edge curve for a metal binding to a bacterial surface. As pH increases, the cell wall deprotonates and adsorption of the positively charged metal cation increases, but in some instances, adsorption may actually decrease at high pH values as metal hydrolysis is enhanced.

Much of our understanding about how bacteria bind metals stems from the pioneering work of Terry Beveridge on metal accumulation by the Gram-positive bacterium, *Bacillus subtilis* (Beveridge and Murray, 1976). His research demonstrated that it was the carboxyl groups within the peptidoglycan that were the most electronegative sites, and that the bulk of the binding capacity was associated with the cell wall. In similar studies with Gram-negative cells, such as *Escherichia coli*, it was demonstrated that they did not bind as much metal from solution as did their Gram-positive counterparts, a pattern stemming simply from the smaller amounts of peptidoglycan associated with the *E. coli* cell walls (Beveridge and Koval, 1981). Many Gram-positive and Gram-negative bacteria also produce extracellular polymers (EPS), and due to their hydrated nature, dissolved metals can freely diffuse throughout the structure, binding to the anionic carboxyl groups of uronic acids and the neutrally charged hydroxy groups of sugars (Geesey and Jang, 1989). By possessing a large and reactive surface area, it is thus not

unexpected that a number of studies have also documented that encapsulated bacteria bind more metals than nonencapsulated varieties (Rudd et al., 1983). Indeed, species producing EPS can tolerate higher metal concentrations than those that do not, and it has been shown that the proportion of encapsulated bacteria increases in metal-polluted sediment, whereas mutants that cannot produce capsules die off (Aislabie and Loutit, 1986).

Irrespective of the bacteria studied, what was repeatedly observed was that considerable variations in metal immobilization could be displayed by a single species. In some instances, cell walls were diffusely stained (Figure 2), while at other times so much metal was fixed to the cell surface that it formed a distinct mineral phase (Figure 3). This led Beveridge and Murray (1976) to originally propose a two-step mechanism for the metal adsorption process; the first step in time is an electrostatic interaction between the metal cations and the anionic sites in the cell wall/EPS. This interaction then acts as a nucleation site for the deposition of more metal cations (and anions) from solution, potentially leading to biomineralization. The size of the deposit depends on a number of variables, including the concentration of ions and the amount of time through which the reactions proceed. If sufficient time exists, then the mineral product grows in size within the intermolecular spaces until it is physically constrained by the organic polymers. The end result is a bacterial wall/EPS that contains copious amounts of metal, often approaching the mass of the bacterial cell itself (Beveridge, 1984).

Microbial-Metal Binding, Figure 1 Generic adsorption curve for a metal cation binding to a bacterial surface. Metal adsorption increases as pH increases and cell wall functional groups deprotonate.

Microbial-Metal Binding, Figure 2 Transmission electron micrograph (TEM) of the lab-cultured cyanobacterium *Anabena* sp. that was stained with uranium acetate and lead citrate to reveal cell ultrastructure. Note the dark staining of the cell wall and some of the cytoplasmic constituents.

Microbial-Metal Binding, Figure 3 TEM image of two unidentified bacteria surrounded by iron-stained extracellular polymers. The dark grains at the top right are ferric hydroxide, $\text{Fe}(\text{OH})_3$. These cells grew naturally in Fe-rich hydrothermal fluids at the Lysuholl hot spring in Iceland. From Konhauser (2007).

Although binding of cations to a microbial surface is largely an electrostatic phenomenon, the structural and compositional complexity of the wall or EPS, as well as the unique physicochemical properties of each element, adds a level of complexity to the overall process. In other words, protons and each different cation should be capable of interacting in a distinctive way with surface ligands, such that a cell's surface will display varying affinities for binding different cations. Moreover, in natural systems, a multitude of cations (and anions) exist that should compete with one another for complex formation. This realization has led to a number of metal binding studies that have compared the relative affinities of protons and various cations for the anionic ligands on the cell surfaces of different microorganisms, by techniques that involve displacing one by another. Those studies have highlighted two very important points, the first being that metals and protons compete for the same surface sites, and as solution pH decreases, the functional groups become protonated, displacing loosely bound metal cations (Fowle and Fein, 2000). The second finding is that microbial-metal interactions are largely abiotic, nonspecific, and reliant upon thermodynamics (Warren and Haack, 2001). Some of the most important factors that influence metal binding to cells are (1) the ionic potential of the solution, (2) cell wall/EPS ligand spacing and their stereochemistry, (3) the ligand composition, and (4) the balance between the initial electrostatic attractions between a soluble metal cation and the organic ligands, and the subsequent covalent forces that arise from electron sharing across a metal cation-ligand molecular orbital (Williams, 1981). These properties are largely understood, and given

sufficient information about the environment in which a microorganism is growing, it is possible to extrapolate and predict metal binding patterns on a cell surface.

In the past decade, metal binding experiments have begun to emphasize the stability constants for metal-organic ligand interactions and elucidate how metal binding correlates with cell surface reactivity during changes in solution chemistry. Moreover, unlike many of the early biosorption studies that were carried out in supersaturated conditions with respect to the metal of interest, more recent studies have focused on describing metal-microbe interactions at more realistic undersaturated conditions. The goal for much of this research is to develop geochemical speciation models that describe how microorganisms interact with metals and mineral surfaces under varying geochemical conditions, thus enabling their use in reactive transport models (Fein, 2000 for review). The reactions can be quantified using two different approaches: (1) bulk partitioning relationships or (2) surface complexation models (SCM). In the first instance, partitioning models, such as K_d , Freundlich and Langmuir isotherms, can easily be applied to complex systems because they do not require a detailed understanding of the nature of the surfaces or the adsorption/desorption mechanisms involved. However, they are system-specific, meaning that the results from a set of experiments can be inapplicable to different systems. In contrast, the SCM takes into account the effects of changing pH, solution composition and ionic strength, the acid-base properties of surface functional groups, competitive sorption with other solutes, and solid-phase reactivity and mineralogy. It then draws upon that information to extrapolate to conditions beyond those tested in the laboratory. However, in order to utilize these models in more complex settings, more detailed understanding is required of not only surface and aqueous speciation but also the adsorption and desorption mechanisms.

New experimental techniques are helping to elucidate both the mechanisms and stoichiometry of metal-microbe interactions. Spectroscopic data provide more direct evidence of the metal coordination environment than traditional SCM and partitioning models. For example, metal binding onto *B. subtilis* has been examined by X-ray absorption spectroscopy (XAS) and provided estimates of metal:functional group stoichiometry (Boyanov et al., 2003; Kelly et al., 2002). Mechanisms of metal binding have been directly probed via time-resolved laser-induced fluorescence spectroscopy (TRLFS) and have shown that some metals preferentially bond to one functionality in the cell wall (Panak et al., 2000), while others are less specific (Texier et al., 2000; Markai et al., 2003). A notable recent advance in constraining the thermodynamics of metal-microbe adsorption reactions was the combination of calorimetric data with SCM to generate site-specific enthalpies and entropies of metal adsorption onto the cell wall of *B. subtilis*. This work indicated that heavy metals bind to the cell wall via inner sphere complexation (e.g., no interlayer water molecules) with multiple anionic

oxygen ligands. Stoichiometry and temperature dependence of the metal–bacteria adsorption reactions can also be extracted using this approach (Gorman-Lewis et al., 2006).

Summary

Microbial–metal adsorption includes the electrostatic and chemical association of metals with the organic functional groups of microbial cell surfaces. This can be considered a passive process driven by the electronegativity of the microbial cell wall/EPS and the Gibbs free energy of the adsorption reactions. These adsorption reactions seem to be dominated by binding of cations to the oxygen containing moieties on the cell surface. Future advances in elucidating the mechanisms of metal adsorption to microbes will come from combining novel analytical techniques, such as colorimetry and spectroscopy, with bulk partitioning studies and site-specific adsorption models.

Definition

Destruction of rocks and minerals by biological activities has been termed bioerosion (Neumann, 1966). It includes mechanical as well as chemical effects, that is, bioabrasion and biocorrosion (Schneider, 1976; Golubic and Schneider, 1979). However, both the processes often co-occur; they are functionally interconnected and mutually supportive. Biocorrosion can result from the activity of macro- or microorganisms and, thus, is called macrobiocorrosion and microbiocorrosion. Microbiocorrosion can also be closely associated with microbial rock formation and consolidation in stromatolitic structures (Reid et al., 2000; Macintyre et al., 2000; Garcia-Pichel et al., 2004; Dupraz and Visscher, 2005). In fact, the oldest known fossils of microboring organisms were located in lithified horizons of silicified stromatolites (Zhang and Golubic, 1987).

MAT-RELATED SEDIMENTARY STRUCTURES

Hubertus Porada
 University of Göttingen, Göttingen, Germany

Synonyms

Microbially induced sedimentary structures (MISS) (The acronym MISS was introduced by Noffke et al. (2001) for “microbially induced sedimentary structures.” Many of the structures addressed, however, are not truly “induced” by microbes, but rather by physical forces

acting on a biostabilized sediment surface or a microbial mat. Since, in this scenario, the biological component significantly influences the shape of evolving structures, it is suggested to write out the acronym MISS as “microbially influenced sedimentary structures.”).

Definition

Mat-related sedimentary structures are small- to medium-scale sedimentary structures resulting from growth and extension of microbial populations and communities on a sediment surface, stabilization of surface sediments, trapping and binding of sediment particles, and from the impact of environmental factors, such as inundation, sedimentary deposition, subaerial desiccation, wind- or current-induced traction, on epibenthic microbial mats.

Introduction

Originally described from and applied to modern microbial mats (Gerdes et al., 2000; Noffke et al., 2001), mat-related sedimentary structures preferentially serve as proxies of the former existence of microbial mats in ancient siliciclastic sediments. Mat-related structures are in a way analogous to trace fossils (Schieber, 2004), whereby the former presence of mats can be inferred, e.g., from observations suggesting “unusual” sediment properties like original cohesiveness, tensile strength, and erosion-resistance of sand (Eriksson et al., 2007); uncharacteristic grain fabrics; and steep geochemical gradients on a mm-scale. Genetic explanation of the structures relies on an actualistic approach; preservation depends on intrinsic biological, and favorable environmental conditions.

In this chapter, the term “mat-related sedimentary structures” is applied to structures that form on, in, or below microbial mats with distinct properties, e.g., coherence, cohesiveness, minor thickness, and adaptation to periodic subaerial exposure. Further conditions include a fine-grained siliciclastic substrate (sand to silt) and lacking dominance of carbonate precipitation. The term also encompasses primary physical structures that have subsequently been microbially influenced.

Today, well-developed (cyanobacterial) microbial mats that meet the above conditions, are observed mainly in the intertidal to lower supratidal zones of low-gradient tidal flats where they grow in a wide range of climate zones from temperate humid to subtropical/tropical semi-arid and arid, at salinities ranging from brackish to hypersaline. Similar mats may also form in other environments, e.g., lacustrine, fluvial, where similar mat-related structures may partly form. Due to lacking vertical bioturbation in the Precambrian, the distribution of microbial mats may previously have been much wider, extending far into the subtidal zone.

Microbial mats are epibenthic, multilayered microbial communities including different functional groups of microorganisms (Stal, 2000) which act together in a kind of “joint venture” widely balancing organic matter production and destruction (van Gernerden, 1993). Thus, microbial mats in coastal environments normally do not

exceed a thickness of a few centimeters. The “biological stratification” of microorganisms is superimposed by a biosedimentary lamination resulting from the interplay of microbial growth and seasonal, periodic, or episodic depositional events related, e.g., to tides or storms.

The top layer of the mat system, which periodically is exposed to the atmosphere, usually consists of oxygenic, filamentous cyanobacteria, frequently *Microcoleus* sp., which form a “felty” fabric of interwoven filaments (Gerdes et al., 2000), including also sediment grains incorporated by “trapping and binding” processes (Noffke et al., 2003a, with references). The felty layer may be overlain, or in some cases replaced, by a resistant (“leathery”) layer of colloid extracellular polymeric substances (EPS) produced mainly by coccoid cyanobacteria. This top portion of the mat combines high mechanical resistance with low permeability and is the locus at which most of the mat-related sedimentary structures form. Deeper levels of the mat system are much less cohesive. They contain anaerobic bacteria among which sulfate-reducing bacteria produce sulfide leading to precipitation of iron sulfides (FeS) which gradually transform into pyrite. In the ancient record, the stratiform occurrence of pyrite, in some cases siderite or ferroan carbonate, within otherwise well oxidized sediments may serve as a proxy of the former existence of microbial mats.

Formation and types of structures

Mat-related sedimentary structures may form during all the stages from first microbial colonization of a sediment surface, through establishment and sustainment of a fully developed mat, to its destruction and final erosion.

Structures related to early microbial colonization

Microbial colonization leads to “biostabilization” (Krumbein et al., 1994) of a sediment surface which then can resist erosion to some degree. This property may lead to “palimpsest ripples” when new sediment is deposited on top a biostabilized rippled surface (Pflüger, 1999); to surfaces with “multi-directional ripple marks” (Noffke, 1998); and to “ripple patches” (Figure 1a) or “erosional pockets” when a biostabilized flat surface or mat is locally eroded (for ancient example, Noffke, 1999; McKenzie, 1972).

Structures related to microbial growth and mat growth

Depending on availability of water for some time, specific filamentous cyanobacteria (e.g., *Lyngbya aestuarii*) start to produce on the mat surface, a characteristic “reticulate growth pattern” of small, sharp-crested ridges stabilized by EPS (Figure 1b). Ancient structures of this type are named “elephant skin” texture (Gehling, 1999) (Figure 1c). There is considerable variability in respect of polygon size (few mm to few cm) and shape varying from nearly circular to narrow rectangular with almost linear crest orientation. A unifying feature, however, are the

narrow, sharp-crested ridges preserved on upper bedding surfaces.

A further type of structures related to mat growth are “mat expansion structures,” collectively termed “petees” (Gavish et al., 1985; Bouougri et al., 2007), which deform the upper, cohesive part of the mat into bulges and domes, thus enlarging the mat surface (Figure 1d). Occasionally, the bulges may be arranged in a polygonal pattern. Provided, petees are filled by sediment rising up from below, the structures may be preserved. Ancient examples have been named “petee ridges” (Schieber, 2004).

Structures related to mat desiccation and shrinkage
Subaerial exposure causes dehydration and shrinkage of the EPS and eventually cracking of the mat. Incipient,

isolated “shrinkage cracks” are sigmoidal and spindle-shaped, or tri-radiate starting from triple junctions, or occasionally circular in shape (Figure 1e). Crack propagation at progressive shrinkage leads to more or less complete networks of cracks. In general, shrinkage cracks in microbial mats develop a higher degree of curving unlike normal mud cracks. Ancient shrinkage cracks are also termed “sand cracks” referring to their occurrence in sandy sediment without shrinkable mud present. A specific type of shrinkage cracks, characterized by sinuoidal or sub-circular trends and developed mainly in ripple troughs, is referred to as “*Manchuriophycus*”-type in the ancient record (Porada and Löffler, 2000) (Figure 1f). A characteristic property of many ancient shrinkage cracks is their easy separability from the layers above and below, which is ascribed to soon microbial

Locality: Terminal Proterozoic Vingerbreek Member, Nama Group; Farm Haruchas, Namibia. (e) Microbial mat, torn and partly removed by current or wind action. Flip-overs of mat margins are indicated by "F." Note small-scale desiccation cracks in exposed mat substratum. Locality: Sabkhet Mjasser, Mediterranean coast of southern Tunisia. (f) "Roll-up" structure ("jelly-roll") consisting of rolled-up microbial mat and adhering sediment. Scale (coin) is 23 mm. Locality: Bhar Alouane, Mediterranean coast of southern Tunisia.

overgrowth of the crack margins and of the sediment trapped in the crack.

Thick mats, frequently dominated by *Microcoleus chthonoplastes*, tend to form polygonal networks of wide cracks with "upturned" or involute, "curled margins" (Figure 2a); individual polygons may range in size from 10 to 60 cm across, depending likely on the thickness of the mat. Ancient examples exhibit a "chaotic" upper surface with irregularly oriented bedding (Figure 2b) and resemble sedimentary structures ascribed to seismic events (Donaldson and Chiarenzelli, 2007).

Thin mats, frequently dominated by coccoid cyanobacteria and vested with a strong EPS top layer, tend

to form circular openings with curled margins around (Figure 2c). Ancient examples have been described from thin siltstone layers within heterolithic deposits (Bouougri and Porada, 2007) (Figure 2d).

Structures related to mat deformation, destruction, and erosion

Cohesive microbial mats may become torn, detached from the substratum and tightly folded, and eventually eroded by strong currents, e.g., during storm and flooding events. Mats are also destructed by complete desiccation after cessation of groundwater supply, and dried mat fragments

may be transported by wind over wide distances and be deposited in environments where mats usually do not grow.

Mat destruction by currents leads to typical structures repeatedly observed in modern environments and in the ancient record: (1) “flip-over” structures (Figure 2e) result when a mat’s edge is flipped over; (2) cigar-shaped “roll-up” structures, also named roll-ups or “jelly-rolls” (Figure 2f), may develop when curled margins or flip-overs undergo additional rolling due to current action; and (3) irregular or arcuate belts of “mat deformation folds” form when a torn and detached mat is crumpled by tractional forces (Figure 3a); similar folds may also result from mat slumping on steep slopes, e.g., along tidal channels. Roll-up structures can withstand transport over some distance and may gather along trash lines, whereas

the other structures largely remain in situ. For ancient examples see Schieber et al. (2007).

“Mat chips” (Gerdes et al., 2000) are small fragments of eroded mats or biostabilized sediment. They primarily are irregular in shape with frayed edges, but may become pebble-shaped with transport (Figure 3b). Ancient examples have been named “microbial sand chips” (Pflüger and Gresse, 1996) or “sand clasts” in contrast to intraformational mud clasts (Figure 3c).

Structures formed beneath microbial mats

From the hydraulic perspective, the sediment beneath cohesive and coherent microbial mats may be addressed and treated as a confined aquifer in which, at sufficient hydraulic head, a potential for liquefaction may develop (Porada et al., 2007). In such case, hydraulic upward

Mat-Related Sedimentary Structures, Figure 3 Structures related to mat deformation and erosion, and subsurface structures. Scale (knife) in a, b, e, and f is 8 cm. (a) Detached, thin microbial mat, torn and strongly deformed by current action. Locality: Coastal sabkha between Gabes and Skhirat, Mediterranean coast of southern Tunisia. Locality: Terminal Proterozoic Vingerbreek Member, Nama Group; Farm Haruchas, Namibia.

pressure will lead to slow, upward movement of sediment grains. As a result, bulges and domes developed in the mat will gradually be filled from below; “petee ridges” have been quoted as an example above.

Thin microbial mats, particularly those dominated by coccoid cyanobacteria, may develop very irregular surfaces with numerous small domes and buckles which also appear as positive features on the subsurface (Figure 3d). Ancient examples of such “subsurface structures” strongly resemble load structures but are clearly distinguished from these by their occurrence as positive features on *upper* bedding surfaces (Figure 3e).

“Kinneyia” (Figure 3f) is a further structure developed in the sediment beneath a microbial mat. The structure is characterized by millimeter-scale, flat-topped, steeply sided, winding ridges separated by equally sized round-bottomed troughs and pits. It resembles small-scale interference ripples including crest-dominated linear and pit-dominated honeycomb-like patterns. The structure has been described from the Archean (Noffke et al., 2003b) to the Jurassic (Bloos, 1976), but not yet from the Recent. Genetic interpretation is thus difficult. Recent models suggest formation by trapping of gas underneath a sealing mat (Pflüger, 1999) or by reversals of groundwater flow in the liquefied mat substratum (Porada et al., 2007).

Wrinkle structures

The term “wrinkle structure” (Hagadorn and Bottjer, 1997, 1999) is currently used as a collective term for various small-scale irregularities developed on ancient, siliciclastic sediment surfaces. Application of the term implies that a microbial participation in the formation of the structure is suspected, at the least. Within this broad definition, wrinkle structures may originate from very different processes including microbial growth, mat deformation and subsurface processes (Porada and Bouougri, 2007). Included in the term are also structures like elephant skin and Kinneyia which are well defined and for which, if clearly identified, usage of the proper name is recommended.

Preservation of mat-related structures

As most of the organic matter produced by the cyanobacteria is soon decomposed and mineralized so that organic components or even carbon are rarely preserved in the ancient siliciclastic record, preservation of mat-related structures is largely dependent on the volume of inorganic material bound or produced by the mat or trapped by the structure. Microbially supported processes introducing inorganic material into the mat include “trapping and binding” of silt- to sand-sized grains and possibly clay minerals, formation of authigenic clay minerals during bacterial lysis, formation of iron sulfides and pyrite, and precipitation of carbonates. The mat-related structures themselves, being either positive or negative features on the mat surface, may act as sediments traps. Thus, shrinkage cracks may become filled with sediment by currents or

colian action, and involute (curled) margins may trap grains in their windings.

Another mechanism by which some mat-related structures, e.g., domes and bulges developed in the mat, may become preserved is “filling from below.” This process requires comparatively high hydraulic upward pressure enabling liquefaction of the sediment below the sealing mat so that grains are lifted and moved upwards. As a result, a previously flat surface of a sedimentary layer may be transformed into an irregular surface mimicking morphological features of the mat.

Conclusions

Simplistically subsumed under the main groups of “wrinkles,” “unusual cracks,” and mat chips in the fossil record, mat-related sedimentary structures exhibit a wide range of shapes and patterns resulting from various processes and interactions between conflicting biological and physical factors. Due to local microtopographic features and the intrinsic inhomogeneity of microbial mats on a small scale, even well-defined structures, like elephant skin or Kinneyia, may show a high degree of variability. Thus, one structure almost never is like the other and the paradigm of reproducibility is not strictly applicable to them. Nevertheless, the structures are distinctive as exemplified on Figures 1–3.

Mat-related sedimentary structures may serve as tools for detailed facies analysis in siliciclastic peritidal settings. Based on modern analogs, most of the structures form in the intertidal to supratidal zones, but mat extent may have been wider in the Precambrian. Structures requiring (at least temporarily) subaerial exposure for their formation, e.g., types of shrinkage cracks with or without upturned or curled margins, clearly indicate intertidal to supratidal positions, whereas others remain less unequivocal. Subsurface structures including Kinneyia may form down to the shallow subtidal zone, as long as coherent, cohesive mats are present.

In the fossil record, the significance of mat-related sedimentary structures increases greatly if several types are observed in association. Some mat-related structures, e.g., reticulate growth patterns, preferentially occur in heterolithic successions of thinly laminated siltstone and mudstone which, in some cases, may be addressed as “siliciclastic biolaminites” resulting from the interaction of microbial mat growth and sediment supply (Bouougri and Porada, 2007), whereas sand cracks are usually developed on sandstone layers intercalated in the succession. In contrast, Kinneyia structures exclusively occur on upper surfaces of sandstone beds which frequently represent event deposits after storms or floods.

METAGENOMICS

Wolfgang Liebl
 Technische Universität München,
 Freising-Weihenstephan, Germany

Definition

Metagenomics is a research discipline that uses molecular biology methods to acquire, analyze, and interpret sequence data and/or functional data from the metagenomes (the collectivity of genomes) present in the environmental samples, without the need to cultivate the organisms in the samples. Related methodologies are so-called metatranscriptomics and metaproteomics that focus on the collective transcriptomes and proteomes, respectively, rather than on the genomes.

Introduction

Microorganisms constitute major life forms on earth with respect to cell numbers and total biomass, and fulfill essential functions in global element cycles. It has been estimated that the earth's biosphere harbors at least two to three orders of magnitude more prokaryotic cells ($4\text{--}6 \times 10^{30}$) than the number of plant and animal cells combined. The total carbon fixed in prokaryotic cells amounts to $3.5\text{--}5.5 \times 10^{17}$ g of C which is 60–100% of the estimated total carbon in plants (Whitman et al., 1998).

For many decades since the beginnings of microbiology, research in this field has depended on the isolation and cultivation of individual microorganisms (best illustrated for the area of medical microbiology with the work of Robert Koch on the isolation and characterization of pathogenic bacteria in monocultures, leading to the Koch's postulates) or well-defined syntrophic consortia, and the subsequent in-depth analysis of pure cultures. Until today, microbiological research with traditional cultivation and

MOLAR-TOOTH STRUCTURE

Brian R. Pratt
 University of Saskatchewan, Saskatoon, SK, Canada

Definition

Molar-tooth structure is a synsedimentary, combined deformation and early diagenetic feature occurring in calcareous strata of mainly Precambrian age. It consists of arrays of closely spaced, sharply defined, upright veins, and subordinate horizontal sheets and spheroids composed of calcite microspar. Veins are vertically to obliquely oriented, discontinuous, typically strongly squashed or crumpled, and often brecciated.

Geological age

Molar-tooth structure (MTS) was first named in 1885 from its appearance on limestone bedding planes in the Mesoproterozoic Purcell Supergroup (= Belt Supergroup in USA.) along the border between southwestern Canada and adjacent northwestern Montana. Almost all occurrences are in Mesoproterozoic to late Neoproterozoic (Ediacaran) strata, representing a 1 billion-year time span from about 1,600 to 600 Ma, but there are several examples noted from the Paleoproterozoic and one from the Neoarchean (James et al., 1998; Pratt, 1998b; Shields, 2002; Meng and Ge, 2002). Importantly, a few Phanerozoic cases have also been reported (Figure 1c; Pratt, 1982; Rossetti, 2000).

Geobiological implications

Organisms and organic matter have been alleged to be implicated in MTS formation in various ways. Its rarity

after the Neoproterozoic has been ascribed generally to substrate modification by animals. However, the drastic reduction of MTS occurrences took place before the known appearance of infaunal invertebrates and, instead, Shields (2002) saw the decline as due to changes in the chemistry of seawater, especially a decrease in CaCO_3 saturation caused by a drop in atmospheric pCO_2 . There may have been an evolutionary control on the shape and mineralogy of lime mud, leading to the precipitation of granular lime mud which was thus prone to fluidization (Pratt, 1998b, 2001). Pratt (1998b) postulated that the rheology of carbonate sediment altered with the changing nature of organic matter and the microbiota brought about by the “Cambrian explosion.” Biomarkers in late Neoproterozoic examples represent cyanobacterial, anaerobic bacterial, and eukaryotic algal precursors in the sediment (Kuang et al., 2004). According to some interpretations, MTS was originally void space created by CO_2 generated by the biodegradation of organic matter

Molar-tooth Structure, Figure 1 (a) Lime mudstone riddled with molar-tooth structure (MTS) veins (dark): initially sparse and upright, passing upward to dense and strongly oblique, thence, in the upper two thirds, to upright but markedly crumpled and tilted. George Formation, Muskwa Group (~1.6 Ga), northern British Columbia. (b) Mudstone with three generations of MTS and erosion surfaces. First-generation veins in lower part are fragmented and reworked while second-generation veins are upright. Lowest erosion surface (vertical arrows) is cusate around upright veins, with vein fragments collected in gutter at left. Overlying mudstone contains third-generation veins that are variably oriented. Second erosion surface (oblique arrows) truncates veins; vein fragments are collected in gutter at left and on horizontal surface at right. Overlying cross-laminated grainstone contains a fourth generation of rare upright veins. George Formation. (c) Wackestone (dolomitic areas light gray) with crumpled veins (whitish). Coronach Member, Herald Formation Red River Group (late Ordovician), 14-26-6-11W2 (2,565.5 m), southern Saskatchewan (see El Taki and Pratt, 2009).

(Furniss et al., 1998; Pollock et al., 2006) or by CO₂-clathrate destabilization (Marshall and Anglin, 2004). James et al. (1998) suggested that a surface microbial mat sealed the sediment. If not physicochemical, precipitation of CaCO₃ crystals in the veins (Pollock et al., 2006) or as sediment grains before being fluidized (Pratt, 1998b, 2001) may have been triggered by dissolved organic molecules, nucleated on organic particles, or induced by photosynthesis.

Shape

MTS occurs mostly in both clean and argillaceous subtidal lime mudstones (Figures 1a–c, 2a and b), but a few are in shales (Figure 2c). Individual vein arrays crosscut up to ~0.5 m of sedimentary bedding; locally, they can comprise more than 50% of the host rock. Veins are discontinuous, range from fairly uniform to variable in width up to ~5 mm along their length, and typically exhibit tapered terminations. Although more or less straight to gently curved in some beds, mostly veins are strongly squashed or crumpled. The whole array may be tilted in one direction. On bedding planes, veins describe variably continuous subparallel, crisscrossing, or irregularly reticulate lines. The upper and lower surfaces of horizontal veins match, indicating that they are dilatational sheet cracks. Crudely spheroidal blobs are up to ~1 cm across. Two crosscutting episodes of vein formation are common, and they typically show differing degrees of deformation. In some argillaceous and silty units, as many as four consecutive phases of vein generation can be delineated, with each containing progressively less calcite and more

terrigenous particles, and consequently appearing less and less distinct from the matrix.

The matrix usually shows soft-sediment deformation especially in the form of small-scale folding. Typically, the matrix along with the enclosed MTS was deformed plastically together. Veins may be dislocated and the segments shingled in both vertical and horizontal directions, but they are also often stretched, boudinaged, or smeared. In many cases, a subsequent event caused the still plastic matrix to be deformed around veins that had become stiff due to calcite cementation, which also resulted in brecciation of the veins. After consolidation of the matrix, a further phase of deformation caused small mode I cracks in the veins but little displacement. These features are evidence for variably directed compressional, tensile and shear stresses that were imposed often repeatedly during the separate rheological evolution of both components.

Seafloor erosion affected many beds with MTS. The more resistant veins commonly protruded above the substrate, and vein segments and fragments were winnowed out and concentrated into interbedded intraclastic grainstones (Figures 1b and 2b). In a so far unique case, cross-lamination in vein fills indicates that they were exhumed and reworked by waves before cementation (Bishop and Sumner, 2006).

Composition

Locally MTS consists of micrite. However, in most cases it is composed of interlocking, equant, inclusion-free microspar crystals 7–15 µm across (Figure 3a). Back-scattered electron microscopy and cathode-luminescence reveal that in some examples these crystals consist of

Molar-tooth Structure, Figure 2 Thin section photomicrographs of molar-tooth structure (MTS) (light gray); scale bar same for all. (a) C_{org}-rich mudstone with densely packed squashed and broken veins, overlain by distorted, laminated mudstone with tilted and crumpled upright and subhorizontal veins. George Formation. (b) Dolomitic mudstone with two crosscutting generations of horizontal and squashed upright veins. In middle, grainstone lamina (composed of micrite peloids and grains of MTS) is crossed by veins and part of its interparticle porosity is filled with microspar. I-5 unit, Atar Group (~1.1 Ga), Mauritania. (c) Slightly calcareous shale with spheroidal and crumpled upright veins. (Vertical crack in center is an artifact.) Chamberlain Formation, Belt Supergroup (1.45 Ga), central Montana.

Molar-tooth Structure, Figure 3 (a) Thin section photomicrograph of calcite microspar in pod-shaped molar-tooth structure (MTS) and smeared, variably distinct, horizontal veins, and stringers; isolated microspar grains are also dispersed in shale matrix. Chamberlain Formation. (b) Back-scattered electron photomicrograph showing microspar mosaic with euhedral mud-sized cores (dark gray). Cores are rhombs and less commonly multifaceted crystals. Monteville Formation, Transvaal Supergroup (~2.6 Ga), South Africa (see Bishop and Sumner, 2006, fig. 9C; photograph courtesy of J. W. Bishop). (c) Thin section photomicrograph of squashed and shingled veins crossing argillaceous lime mudstone overlain by sandstone. Veins contain quartz silt and very fine-grained sand (whitish grains near the sandstone and sourced from it; those elsewhere are authigenic quartz crystals). Helena Formation, Belt Supergroup, northwestern Montana.

well-sorted rhombs and multifaceted euhedra with calcite cement overgrowths (Figure 3b; Pollock et al., 2006; Bishop and Sumner, 2006). These cores may be the original mud particles or a product of syndimentary recrystallization. Similar grains occur in the matrix mudstone or shale. Microspar in MTS is typically uniform in size but locally there is variation that describes crude wall-parallel lamination; indistinct shear veins or cracks can be detected in some examples. In some units the MTS is recrystallized to pseudospar.

Where veins penetrate interbedded siltstone or sandstone layers the microspar may contain silt or fine sand plus minor amounts of clay (Figure 3c; Pratt, 1998b, 1999; Bishop and Sumner, 2006). MTS may grade into dikelets and thin sills of injected silt and sand of the kind that have been termed “syneresis” cracks (Pratt, 1998a; cf. Tanner, 1998; Shi et al., 2009).

The calcite in MTS exhibits $\delta^{13}\text{C}_{\text{PDB}}$ values in the range of about -1.5‰ to 3.5‰ , which are similar to those in co-occurring sedimentary carbonate particles (Frank and Lyons, 1998; Pratt, 1998b; Marshall and Anglin, 2004; Bishop et al., 2006; Kuang et al., 2007).

Formation

For more than a century, the enigmatic nature of MTS was tolerated but largely ignored. Because fragments of MTS comprise sedimentary particles, it was eventually recognized as having formed intrastratally just below the sediment–water interface. Some geologists presumed MTS to be a fossil algal or microbial object. Later it was accepted as a deformation feature involving substantial shrinkage of the host sediment – although not due to desiccation because there is no evidence for associated subaerial exposure.

Pore-lining cement fabrics are absent in MTS even though they are present in co-occurring grainstones. Nevertheless, it is still debated whether or not MTS was initially a system of cavities, in which case CaCO_3 precipitated later as tiny crystals inside them (Fairchild

et al., 1997; Furniss et al., 1998; Pollock et al., 2006; Bishop and Sumner, 2006; Bishop et al., 2006). The presence in MTS of sand, silt, and clay impurities as suspended particles, clusters of grains, or seams is difficult to reconcile with this interpretation.

The possibility that MTS began as voids forced open by bubbles of CO_2 passively generated by the oxidation of organic matter in the sediments is unlikely because of the extreme amount of organic matter required, the shallow-water, oxidizing depositional setting, the linear to reticulate shape of vein arrays, the evidence for concomitant sand and silt injection, and the complex nature of the stresses demonstrated by accompanying physical deformation (Pratt, 1999). Because of the tropical sedimentary environment of host limestones, the involvement of CO_2 -clathrates is implausible. In most units, the absence of closely associated high-energy features is further evidence against the possibility of void opening by wave-induced loading (Bishop et al., 2006).

Pratt (1998b) explained MTS as a seismically induced deformation feature of calcareous sediment possessing unique geotechnical properties for which modern analogues are lacking. By this model, cyclic loading during earthquakes caused elevated fluid pressure and loss of shear strength in the muddy sediment. During abrupt dewatering, veins, sheet cracks, and spheroidal pockets were jacked open by the injection of granular lime mud that was segregated from the sediment. Examples where more than 50% of limestones consist of MTS indicate that a substantial proportion of the lime mud was mobilized. However, shaly host rocks still contain poorly defined seams and residual disseminated calcite grains that did not find their way into veins. Incorporated sand and silt show that dewatering and injection were both downwardly and upwardly directed. Spheroids formed where dewatering was localized and fluids did not escape to the surface. All this caused a striking shrinkage of the matrix and compaction of upright veins. As shaking proceeded,

they were squeezed, sheared, and stretched in different directions. After cementation of the mud infill, subsequent events deformed the matrix again, generated more veins, and brecciated the first set of veins, until the sediment was too stiff to deform further. Indeed, in almost every case, distortion of MTS and the matrix testifies to differential rheologies and progressive evolution from liquefaction through plastic deformation to brittle failure, as would be expected if affected by repeated earthquakes during dewatering and early diagenesis. A similar seismic model has been invoked for sand and silt dykelets (syneresis cracks), except that synsedimentary cementation was not involved (Pratt, 1998a).

Definition

Moonmilk is a carbonate deposit that occurs within various subterranean systems. Moonmilk has a white to gray color and, in contrast to rigid cave deposits (*speleothems*) such as stalactites and stalagmites, exhibits a soft, muddy texture of microcrystalline aggregates. These aggregates are mainly composed of calcite, and to a lesser extent of aragonite, monohydrocalcite, hydromagnesite, sulfates, and nitrates (Martínez-Arkarazo et al., 2007; Richter et al., 2008; Cañaveras et al., 2006; Borsato et al., 2000). The calcite shows an aragonite-like needle form (“lublinite”), which is normally associated

they were squeezed, sheared, and stretched in different directions. After cementation of the mud infill, subsequent events deformed the matrix again, generated more veins, and brecciated the first set of veins, until the sediment was too stiff to deform further. Indeed, in almost every case, distortion of MTS and the matrix testifies to differential rheologies and progressive evolution from liquefaction through plastic deformation to brittle failure, as would be expected if affected by repeated earthquakes during dewatering and early diagenesis. A similar seismic model has been invoked for sand and silt dykelets (syneresis cracks), except that synsedimentary cementation was not involved (Pratt, 1998a).

Definition

Moonmilk is a carbonate deposit that occurs within various subterranean systems. Moonmilk has a white to gray color and, in contrast to rigid cave deposits (*speleothems*) such as stalactites and stalagmites, exhibits a soft, muddy texture of microcrystalline aggregates. These aggregates are mainly composed of calcite, and to a lesser extent of aragonite, monohydrocalcite, hydromagnesite, sulfates, and nitrates (Martínez-Arkarazo et al., 2007; Richter et al., 2008; Cañaveras et al., 2006; Borsato et al., 2000). The calcite shows an aragonite-like needle form (“lublinite”), which is normally associated

with soil bacteria. The crystal needles have a diameter of about 0.1 μm and a length of ca. 8–10 μm . The name “moonmilk – Mondmilch” is derived from the name of a cave, “Mondmilchloch,” located at the Pilatus mountain (Emmental Alps, Switzerland) (Fischer, 1988).

Geobiological implications

Moonmilk differs in many aspects from the traditional cave carbonates such as stalagmites and stalactites (Moore and Sullivan, 1997; Bögli, 1978). Its formation is strongly influenced by microbial activity, as suggested by the presence of microbial aggregates, biofilms, and/or fungal mycelia (Cañaveras et al., 1999, 2001, 2006; Borsato et al., 2000; Gadd, 2004; Burford et al., 2003). Moonmilk is a result of (1) microbially mediated weathering and *microbiocorrosion* of carbonate host rock under highly humid conditions and (2) microbially mediated reprecipitation of various carbonate minerals. After dissolution of the mineral components, the residue exhibits high amounts of organic remains. Besides many fungal and actinomycetes, the bacterium *Macromonas bipunctata* plays a major role in the formation of moonmilk. *M. bipunctata* is a lophotrichous, heterotrophic and strictly aerobic betaproteobacterium that has been classified as a colorless sulfur bacterium capable of oxidizing sulfide (Dubinia and Grabovich, 1984). Within *extracellular polymeric substances (EPS)* of *M. bipunctata* and further microbes, calcite seed nuclei are formed to precipitate “lubinite” moonmilk crystals. *M. bipunctata* was originally described as *Pseudomonas bipunctata* by Gicklhorn (1920) and renamed by Utermöhl and Koppe (1924).

MUD MOUNDS

Marta Rodríguez-Martínez
 Universidad de Alcalá, Alcalá de Henares, Madrid, Spain

Synonyms

Biodebital mound; Carbonate mounds; Carbonate mud mound; Lime mud mound; Microbial mound; Mudbank; Reef mound; Stromatolite mounds

Definition

Mud mounds are biosedimentary buildups, part of the reef system and are dominated by fine-grained carbonates (up and more than 50% of rock volume), which form heterogeneous polygenetic matrix-supported fabrics (stromatolitic, thrombolitic, leiolitic, fenestral, laminar, reticulate, stromatolite, etc.). These fabrics are composed of both allomicrites and automicrites (abiogenetic, biogenetically induced, and biogenetically controlled). Production and accretion mechanisms in mud mounds are varied and not always clear, but are associated with the activity of microbial benthic communities (in different degrees of participation). Metazoans, being important colonizers, can or cannot occur but never produce a primary skeletal framework. Mud mounds colonized the oceans from the Proterozoic times, and they grow up from deep aphotic basinal settings to shallow water platforms.

with soil bacteria. The crystal needles have a diameter of about 0.1 μm and a length of ca. 8–10 μm . The name “moonmilk – Mondmilch” is derived from the name of a cave, “Mondmilchloch,” located at the Pilatus mountain (Emmental Alps, Switzerland) (Fischer, 1988).

Geobiological implications

MUD MOUNDS

Marta Rodríguez-Martínez
 Universidad de Alcalá, Alcalá de Henares, Madrid, Spain

Synonyms

Biodebital mound; Carbonate mounds; Carbonate mud mound; Lime mud mound; Microbial mound; Mudbank; Reef mound; Stromatactis mounds

Definition

Mud mounds are biosedimentary buildups, part of the reef system and are dominated by fine-grained carbonates (up and more than 50% of rock volume), which form heterogeneous polygenetic matrix-supported fabrics (stromatolitic, thrombolitic, leiolitic, fenestral, laminar, reticulate, stromatactoid, etc.). These fabrics are composed of both allomicrites and automicrites (abiogenetic, biogenetically induced, and biogenetically controlled). Production and accretion mechanisms in mud mounds are varied and not always clear, but are associated with the activity of microbial benthic communities (in different degrees of participation). Metazoans, being important colonizers, can or cannot occur but never produce a primary skeletal framework. Mud mounds colonized the oceans from the Proterozoic times, and they grow up from deep aphotic basinal settings to shallow water platforms.

Evolution of the term mud mound

Probably, the core of the Silurian Wabash buildup (Indiana, EEUU) was the first carbonate deposit referred to in the literature as a “carbonate mud mound” and was described as a mound of calcisiltite containing crinoid, bryozoan, ostracode bioclastics, and stromatactis, but essentially no stromatoporoids or corals (Textoris, 1966). The Silurian mud mound facies were compared by Textoris with similar buildups reported from other parts of the world (Devonian of Canada, Carboniferous of Europe and EEUU).

When reefs turned mud mounds

In the 1960s, the lack of a recognizable skeletal framework in these buildups pointed out their differences with the “classical” reef idea. During some years, most works on mud mounds were focused on the study of their scarce fauna and few were mentions to the origin of the carbonate mud, paradoxically the main component. Wilson (1975) extended in his book the definition and denomination of “lime mud mound” to many other Phanerozoic buildups, which were seen as dominated by detrital, bioclastic micrites with minor organic boundstone and *perceived to accumulate both through hydrodynamic processes and in situ organic production*. Thus, during the 1970s, the origin of the matrix was explained by the baffling theory: the carbonate mud, externally produced, was baffled by metazoans (crinoids, bryozoans, sponges, etc.). The role of early submarine cementation was also taken into consideration to explain the stabilization of mud mound depositional slopes. Baffled micrites and subsequent cementation was the proposed origin; thus, mud mounds were compared with very different types of Holocene buildups: shallow-water seagrass mudbanks and deep-water coral lithoherms.

When some mud mounds turned into microbial reefs

From the 1970s to the 1980s, some fabrics and textures present in the mud mounds were related with “cryptalgal” and other biosedimentary structures as stromatolites and thrombolites (Monty, 1976; Pratt, 1982). The mud mound matrix could be now bound, trapped, and precipitated by the activity of microorganisms (“blue-green algae” – cyanophytes and cyanobacteria).

From then, the source or origin of the carbonate mud, the matrix problem, will be the leitmotiv in the study of mud mounds. Bosence et al. (1985), from the recent carbonate mounds from Florida Keys, proposed three mud mound models based on the relation between the external and the internal sediment (carbonate mud) supplies in the mound: export, import, and self-sufficient models, respectively. From the 1970s and clearly in the 1990s, mud mounds began to be seen as “self-sufficient” mounds, and the role of microbial communities in their construction gained more importance (Tsien, 1985; Lees and Miller, 1985; Camoin and Maurin, 1988).

James and Bourque (1992) proposed a conceptual classification of reefs and “mounds,” where mounds are *those structures which were built by smaller, commonly delicate and/or solitary elements in tranquil settings*. They differentiated three types of mounds: “microbial” mounds, “skeletal” mounds, and “mud” mounds. Microbial and skeletal mounds are grouped into “biogenic mounds” because they are organically controlled, whereas the term “mud mound” was restricted by the authors to those *formed by inorganic accumulation of mud with variable amounts of fossils*. The authors pointed out that *the division between biogenic mounds and mud mounds depends on the nature of the accumulation/construction controls, not on the percentage of fossils*.

One of the main outstanding questions concerning the mud mounds is related to the modes of formation of the carbonate mud matrix and their recognition. The increase in the number of studies on microbial carbonates and their formation and fabric classifications (Kennard and James, 1986; Burne and Moore, 1987; Riding, 1991) led to new horizons in the matrix problem. Fabrics and geochemical signatures from automicrites of recent cryptic microbialites and controls in their formation (Reitner, 1993) were found to be similar to those recorded in Cretaceous and Jurassic mud mounds (Neuweiler, 1993; Keupp et al., 1993; Reitner et al., 1995; Leinfelder and Keupp, 1995). Thus, modern automicrites began to be used as modern counterparts of some mud mound end products.

Some authors began to use the term mud mound in a descriptive nongenetic way as *carbonate buildup consisting of more than 50% of mud and/or peloidal mud* (Reitner and Neuweiler, 1995), having depositional relief, and forming part of a polygenetic and continuum spectrum ranging from “biodepitril” to “microbial” mud mounds (Bosence and Bridges, 1995). Pratt (1995) considered mud mounds as ecologic reefs because they possess “rigid frameworks” produced by both microbial activity and syndimentary cementation.

Last formal definition of mud mound has been given by Riding (2002), as *carbonate mud-dominated (micrite and fine-silt) deposits with topographic relief and with few or no stromatolites, thrombolites, or in-place skeletons*. Riding added that *the deposits can be organic and/or inorganic in origin and it can be difficult to distinguish their origins*.

General features

Mud mounds have varied external forms; the term mud mound is used here not in a morphological way due to the fact that not all of them are mounds or dome-shaped; they can be tabular-shaped and can occur as isolated massive bodies or as stacked or amalgamated bodies, spreading over kilometers. The biggest mud mound complex is the Waulsortian mudbank from Ireland.

They could develop as a high syndimentary relief and show depositional dips from 10° up to 50°, can be or cannot be flanked by bioclastic limestones, and grow up from

basinal to platform settings. Mud mounds are composed mainly of fine-grained carbonate-matrix-supported fabrics, which are called, depending on the classification schemes followed, mudstones, wackestones, biomicrites, etc. These carbonate muds are texturally and genetically varied. The presence of cavities can be a characteristic feature in some mud mounds. Their macrobiota are diverse and can be important volumetrically in some mounds, although they never constitute a skeletal framework.

Types of carbonate muds

Carbonate muds are formed by pure aphanitic micrites and/or mixture of silt-sized calcite particles (up to 62 μm) as peloids. Then, they can be texturally grouped into aphanitic and peloidal micrites. Both types occur separately, or there is grading between them; they also occur as neomorphosed microspars. Microstructurally, they appear as dense and/or clotted/grumular/spongiostromic microfabrics, which constitute at mesoscale, stromatolitic,

thrombolitic, fenestral, and/or cryptalgal/cryptomicrobial/leiolitic fabrics (summarized in Riding, 2000).

The carbonate muds can be classified in relation to the *locus* of their production. The muds externally produced and later imported into the mound are named allomicrites (Figure 1). They are stabilized at mound surface by mound biota (eukaryotes and prokaryotes) through baffling, trapping, and/or binding mechanisms and early cementation.

The in situ produced carbonate muds are named automicrites. They are formed through abiogenic, biologically induced, and biologically controlled mechanisms (summarized in Flügel, 2004). The biologically related mechanisms are known as nonenzymatically and enzymatically controlled carbonates. Mud mounds seem to be specially dominated by the nonenzymatically carbonate production of automicrites via nonliving substrates (organomineralization of the organic matter derived from decaying organisms) and/or via metabolic processes (by heterotrophic, chemolithotrophic, and phototrophic bacteria and cyanobacteria). In the first case, the

Mud Mounds, Figure 1 Relationships between the mud mound biota and carbonate mud stabilization and production processes.

resulting automicrites are known as organomicrites. The automicrite production occurs at mound surface as well as at subsurface.

The mud mound system comprises both soft (allomicrites and automicrites) as well as firm/early indurated carbonate muds (automicrites), which can suffer from reworking processes (chemical, physical, and/or biological ones) resulting in parautochthonous muds. These secondary muds or the next successive generations of in situ muds, therefore, resemble a mixture of previous ones. This system should be analyzed as a continuous series of processes of automicrite production, allomicrite input, and internal reworking.

The filling of mound cavity system records many of the last mud mound synsedimentary episodes: (1) the entry of allomicrite by gravity or currents, (2) the colonization by cryptic biota, (3) production of automicrites, (4) reworking processes, and (5) the early marine cementation phases as well as burial-related phases.

So mud mounds have polygenetic carbonate mud-dominated fabrics resulting from automicrites production, allomicrites input, and recycling processes (Figure 1). But some microfabrics have been related at the same time with different types of biogenic as well as abiogenic processes, and discriminating between some processes and their products is not always possible.

Mud Mounds, Figure 2 Microbial mat-based model for accretion of mud mounds and development of cavities. (Modified from Pratt, 1982.)

Biota

Dominant invertebrate macrofossils on mud mounds were suspension feeders as pelmatozoans, bryozoans, and sponges – siliceous and calcareous types, although others such as brachiopods, molluscs, and arthropods could be sporadically important. Solitary and colonial corals occasionally occurred on mud mound records as well as calcareous algae, but they were much less common (not as colonizers of the shallow-water mud mound phases). Others such as benthic foraminifera and polychaete worms also occurred as part of the mud mound biota from the Carboniferous times. In general, the biota of mud mounds was mainly dominated by heterozoan assemblages.

In mud mounds, excluding the evident microbial fabrics (stromatolitic, thrombolitic and others), the main signal or product of microbial activity is hidden in the carbonate mud (biogenic automicrites) and in some authigenic mineralizations (iron pigments, Fe/Mn surfaces, framboidal pyrites, etc.). There is also direct evidence of calcified microbes (*Girvanella*, *Renalcis*, *Epiphyton*, *Bacinella*, *Rivularia*-like forms, etc.), and most of them have been interpreted as cyanobacterial fossils. Other evidence of microbial activity is the presence of unidentified filament-rich microfibrils, filaments and spherulites as moulds or casts, and peloids.

Sponge–bacterial assemblages have also played an important role in the initiation and first stages of many mud mound developments (early cementation of sponge tissues is related with the activity of symbiotic bacteria as well as the organomicrite production through the decaying of their tissues).

Cavities

There is a wider spectrum of cavity types in mud mounds (stromatactis, zebra, irregular, and sheet-like shapes). Probably, the most famous are the stromatactis, with smooth, flat base and irregularly digitate roofs, matrix-supported in general, although some can be partially or totally sheltered by remains of fossils. Filled with centripetal marine fibrous cement crusts and varied internal sediments (allomicrites and automicrites), stromatactis were abundant in Paleozoic mud mounds, especially from the Ordovician–Mississippian interval.

The origin of stromatactis has been largely debated, and today it remains controversial. Several hypothesis has been used (summarized in Flügel, 2004, 194 p.), which can be grouped in “organic” (recrystallized fossils, related with decaying organism, burrowing, etc.) and “inorganic” theories (dissolution, collapse, internal erosion between submarine crusts or bioclasts, dewatering and compaction of the muds, recrystallization, enlargement of preexisting cavities, presence of gas hydrates, etc.). In the organic cases, there are two models: the cryptalgal/microbial mat model and the sponge model.

The microbial mat model was initially proposed by Pratt (1982) to explain the mud mound accretion and its

final observed fabrics (Figure 2). The fabrics and the resulting cavities were the result of the combination of three variables: (1) the distribution of the microbial mat, (2) the rate of sediment loading onto the mat, and (3) the degree of winnowing. The distribution of the microbial mat (laterally continuous or in patches) produces the resulting fabrics (laminar or reticulate, respectively). The winnowing of the unconsolidated sediment between the microbial bounds and cemented sediment produces the cavities.

In the sponge model (Bourque and Boulvain, 1993), the cavities are formed by the partial collapse of the sponge body as result of early diagenetic processes through four stages (Figure 3): (1) zone of the living community, (2) zone of sulphate reduction, (3) zone of oxidation of ferrous iron, and (4) zone of marine cementation. In the living surface, the mud is trapped by sponges and/or produced by microbial activity. Below the surface, the microbial decay of sponges occur; part of the sponge body and the mud are cemented, and other sponge parts are in collapsed state; the later internal erosion of the unconsolidated material produces the open cavities. A few meters

Mud Mounds, Figure 3 Sponge model for the Paleozoic red stromatolitic mud mounds. (Modified from Bourque and Boulvain, 1993.)

below, in the ferrous iron oxidation zone began the incipient marine cementation of these cavities forming the stromatactis.

Types of mud mounds through the Phanerozoic record

The classification and distribution of mud mounds through the record depend on the “mud mound versus reef concept” of almost each researcher and thus remain controversial in several aspects. Mud mounds have existed from Proterozoic times and through the Phanerozoic record (see reviews by Monty, 1995; Pratt, 1995), and important growth episodes occurred in early Cambrian, late Devonian, and Mississippian times. Cambrian to Ordovician mud mounds (Figure 4) were characterized by different fabrics and assemblages (stromatolitic, thrombolitic, and massive fabrics with calcimicrobes, and cambrian archaeocyathid/sponge-calcimicrobial

assemblages). From the Ordovician to the Mississippian, some of the carbonate mud-rich buildups, which typify this interval, have been regarded as the classical massive mud mounds with abundant stromatactis (Figure 4) as the ‘red stromatactis mounds’ (Recif Rouges-type mound) and the Waulsortian mudbanks (Figure 5a and b). Clear microbilite-related fabrics (stromatolites and thrombolites) are extremely rare in classical mud mounds, although they show other nonskeletal reef frameworks (calcimicrobial and biocemenstones *sensu*, Webb, 1996), as well as filaments and some characteristic features (clotted, peloidal micrites, and fenestral microfabrics). The parallel diversification of skeletal mound macro- and micro-biota produced more varied metazoan–microbialitic assemblages. One of the most persistent through the mud mound record is the sponge–microbialitic association, very common in Jurassic mud mounds as well as in the deeper initial stages of many Paleozoic mounds. Early Cretaceous is considered the last significant moment of organomineralic mud mound development (Neuweiler et al., 1999), although

other authors mentioned that the latest mud mounds are Miocene (Pratt, 2000).

Ecological zonation models

The Récifs Rouges-type mounds and the Waulsortian mudbanks are probably the most famous and are well known as “classical mud mounds” (Figures 4 and 5) Devonian (Frasnian) mounds from Belgium show a shallowing upward succession from deep basal greenish-grey shales through their mud mound facies: red lime mudstones to wackestones with stromatactis, pink wackestones with millimeter stromatactis to crudely bedded grey wackestones to packstones, and bindstones, and their associated biota. Similar facies (red stromatactis mounds) and assemblages have been found in other mud mounds through the Paleozoic record (Bourque, 1997). The carboniferous Waulsortian mudbanks of Belgium show a four grain-type assemblages related with the growth of these mounds from deep subtidal, aphotic to photic conditions. A depth-related phase model was recognized by Lees and coworkers (summarized in Lees and Miller, 1995) and applied to Waulsortian mudbanks of Europe and North America. Bourque (1997) compared Récifs Rouges-type mounds from Silurian of Canada and Devonian of France and Belgium with carboniferous mounds from Algeria and the Waulsortian mudbanks model and established an ecological zonation model formed by four benthic communities zones (Figure 6): (1) the sponge zone, (2) the fenestellid–sponge zone, (3) the delicate skeletons–sponge zone, and (4) the delicate skeletons–microbial encrusters zone.

Controlling factors

Today, many parameters about the initiation, accretion, and spread of many mud mounds seem to be enigmatic. However, some others begin to be more clear.

Locations of some mud mounds have been related with submarine cold seeps, vents, faults, halokinetic and argilokinetic settings, and local antecedent topographic irregularities, have been associated to nutrient-enriched areas (by endo-, down- and/or up-welling currents), and could be also related with stratified basin waters and fluctuating oxygen minimum zone. Many of them grew up into aphotic to disphotic depths (more than 200 m); however, they could reach and colonize the euphotic zone. Some grew at lower sedimentation rates and/or during sedimentary starvation during TST episodes, although this is not a general trend for all of them. Most of these factors are oceanographic and/or tectonically basin-related parameters and could co-occur together in many cases.

Those factors (biological and chemical parameters) associated with the carbonate mud precipitation related with eukaryotes and prokaryotes should be taken into consideration:

- Production of acidic organic macromolecules (AOM) and an increase in carbonate alkalinity via (1) bacterial heterotrophic pathways (ammonification and sulphate reduction), (2) carbonate, and (3) silicate weathering. AOM and high alkalinity favor the organomicrite production in microbialites and mud mounds (Reitner and Neuweiler, 1995).
- Extracellular polymeric substances (EPS)-biomineralization of microbial mats and biofilms.
- Calcification of cyanobacteria.

Conclusions

Mud mounds are considered mainly as nonenzymatic carbonate deposits that formed a polygenetic and very continuous record of buildups through the Phanerozoic and reached a maximum development during the Paleozoic times. They are of considerable importance not from an economic point of view (hydrocarbon reservoirs, major mineral host-rock and base deposits, ornamental rocks) alone. In fact, they represent an excellent record for the study and establishment of (1) the interactions between the marine microbial and nonmicrobial benthic communities (paleoecologic and paleoenvironmental parameters), (2) marine carbonate production models (mud mound factory), and (3) proxies in palaeoceanographic reconstructions (nonenzymatic carbonates are formed in equilibrium with ambient sea water).

Mud mounds are characterized by different modes of carbonate mud production (abiogenic, biologically induced, and biologically controlled automicrites) and sedimentation input (allomicrites). The key of mud mounds understanding lies behind here: to recognize and differentiate between the automicrite and allomicrite relationship and their contribution to the mud mound accretion.

Synonyms

Living nanovesicles; Nanobes; Nanocalcifying particles (NCP); Nanoforms; Nanoglobules; Nanons; Nano-organisms; Nanoparticles

Biologists used the word *nanobacteria* to describe organisms that possibly enhance biomineralization such as that of kidney stones in humans, whereas *nannobacteria* is used by geologists for organisms responsible for mineral precipitation in terrestrial and extraterrestrial rocks.

Definition

Nan(n)obacteria are tiny globular objects, ranging in diameter from 20 to 200 nm, with the ability to nucleate minerals. They are the smallest known, self-replicating particles with slow growth rate. Because they are by definition down to 1/10 the size of bacteria, it raises the problem of whether or not an organism of this size is large enough to house necessary cell components such as DNA, RNA, and plasmids.

Introduction

The term “nan(n)obacteria” has been originally proposed by Folk (1993) to describe 20–200 nm wide nanovesicles observed in carbonates using scanning electron microscopy (SEM). Kajander and Çiftçioglu (1998) defined the role of similar tiny particles in kidney stone formation. Based on their mineralogical properties, nan(n)obacteria have also been called calcifying nanoparticles (CNP) by

these authors. Nan(n)obacteria-like particles have been observed in Martian meteorites, thereby raising questions about a primitive form of life (Bradley et al., 1997). CNP are studied extensively in pathogenic diseases as infectious agents by nucleating crystals (hydroxyapatite). Therefore, some comparisons have tentatively been made with the geological record. Although they display some evidences of bacterial nature, their living status is subject to controversy because of their small size and the fact that DNA extraction remains unsuccessful. On one hand, biologists discuss their metabolic existence and on the other hand geologists argue for widespread organic fossilization in palaeoenvironments. When interrelations between geology and microbiology are possible, they are looked at only from the point of view of experimental procedures (e.g., one emphasizes the use of DNA probes in geological samples). This prohibits an objective comparison of these very small particles.

Reported nan(n)obacteria in the literature

In the geological record, nan(n)obacteria-like particles are encountered mainly in carbonates: in calcite (Dix et al., 1999; Chen et al., 2005; Mamet and Pr  at, 2006), microbialites (Camoin et al., 1999), dolomite (Figure 1; Vasconcelos et al., 1995; Gournay et al., 1999; Wright, 1999; Al  i  ek, 2009), hydrothermal springs (Casanova et al., 1999), and oncolite laminations (Cavalazzi et al., 2007). They have also been observed in sandstones without mineral precipitation (Uwins et al., 1998) and on quartz overgrowth in crude oil (Spark et al., 2000).

In medical biology, CNP have been the focus of numerous studies on various pathogenic diseases (see Urbano and Urbano (2007) for a review), for example, gallbladder (Wang et al., 2006), nasopharyngeal cancer (Zhou et al., 2006), and renal stone formations (e.g., Kajander and   ift  ioglu (1998) and Jones et al. (2009)).

Characterization of purported nan(n)obacteria

Nan(n)obacteria exhibit some characteristics, which seem to correspond to the classical criteria indicating a biological origin: (1) a typical bacterial appearance (Kajander and Çiftçioglu, 1998; Uwins et al., 1998); (2) a slow growth in liquid cell culture media; (3) an expression of specific antigens (Hjelle et al., 2000; Miller et al., 2004) by using monoclonal antibodies commercially available through Nanobac Oy (Finland) as 8D10 and through Santa Cruz Biotechnology, USA, named GM-CSFR α ; (4) a staining with nucleic fluorochroms (Uwins et al., 1998; Miller et al., 2004) using 4',6-diamidino-2-phenylindole (DAPI), acridine orange, Hoechst 33258, Feulgen, and/or Picogreen; (5) a resistance to antibiotics such as tetracycline and citrate (Maniscalco and Taylor, 2004); (6) a sensitivity to calcium-chelating agents (Rawal and Pretorius, 2005); and (7) a DNA sequencing tentatively assigned to the α -2 subgroup of proteobacteria, which also includes *Brucella* and *Bartonella* species occurring within and outside of host cells (Kajander and Çiftçioglu, 1998; Çiftçioglu and Kajander, 1998). According to Cisar et al. (2000), they could come from PCR contaminant.

Possible origins for nan(n)obacteria

Due to the very small size of purported nan(n)obacteria, the hypothesis that they might represent living entities is very controversial. Several, alternative origins have been proposed:

Inorganic origin: Inorganic precipitates (Vecht and Ireland, 2000; Cisar et al., 2000) and artifacts due to sample preparation (e.g., coating for SEM, acid treatment, polishing artifacts) have been considered as an alternative origin for these nanostructures. However, nanostructures

Nan(n)obacteria, Figure 2 Chain of dolomite nanoglobules formed in *Halomonas meridiana* culture. (Picture courtesy of Monica Sanchez-Roman.)

can also be observed in samples that have not been exposed to these techniques (Folk and Lynch, 1997).

Extracellular polymeric substances (EPS): Reitner et al. (1995) have proposed that nanospheres were an initial calcification of EPS. They have been interpreted as early stages of dolomite precipitation in anaerobic cultures (Bontognali et al., 2008) and aerobic cultures (Figure 2; Sanchez-Roman et al., 2008). Similar observations have been made on aragonite nanocrystals that contained organic molecules (Benzerara et al., 2006).

Proteins: Tissue degradation caused by microbial activity can create nanobacteria-like particles of proteinous origin (Schieber and Arnott, 2003). In the case of kidney stones, it has been confirmed that nan(n)obacteria are in fact related to blood proteins (Martel and Young 2008), that is, fetuin (Raoult et al., 2008).

Small bacteria: Dwarf bacteria generally show a decrease in cell size. This is assumed to be the case of bacteria exposed to low nutrient or starvation conditions (Velimirov, 2001). Ultramicrobacteria exhibit a very low growth rate (Torrella and Morita, 1981). The distinction between ultramicrobacteria and starvation forms is based on their physiological properties (Velimirov, 2001).

Viruses: Stressed bacteria overproduce vesicles that are apparently used to selectively eliminate unwanted material, for example, unfolded proteins (Soler et al., 2008). All fluorescent small-size particles are assumed to correspond to a DNA virus (Soler et al., 2008). Membrane vesicles seem to be produced by most bacteria and have been

detected in natural environments, including biofilms (Schooling and Beveridge, 2006).

Minimal conditions for a living cell

Theoretical calculations have been made in order to define the smallest size needed for a cell to have metabolic processes and accommodate the smallest genome. According to these assumptions, the minimal cell size should fall within the range of 100 nm (Boal, 1999), 140 nm (Maniloff et al., 1997), and 170 nm (Adams, 1999). Assuming a cell genome housing 250 genes (which is considered the minimal number needed to support heterotrophic cell growth in a nutrient-rich environment with a minimal metabolic pathway), a minimum diameter of 50 nm has been established, which could contain eight genes (Adams, 1999). Nevertheless, a cell with a size of only 50 nm, a 5 nm cell wall, 2 ribosomes, 520 protein molecules, and a DNA strand containing 8 genes is considered too small to function like recent bacteria, based on the smallest known living organism, that is, *Nanoarchaeum equitans* (Huber et al., 2002).

Universal origin for nan(n)obacteria?

The analogy between nan(n)obacteria-like particles in pathogenic diseases and geological records is often made even though the methodology differs. Nan(n)obacteria have not been found in any clinical condition that does not involve calcification, which is not the case of some geological samples (Uwins et al., 1998; Schieber and Arnott, 2003). Recently, nan(n)obacteria-like particles associated with kidney stone formation have been assigned directly to blood proteins reacting with antibodies that were so far claimed to be specifically associated to nan(n)obacteria (Martel and Young, 2008; Raoult et al., 2008). The latter authors suggested that they are nucleic-acid free. An alternative origin has been proposed where nan(n)obacteria could be the by-product of the living activities of bona fide bacteria inhabiting kidney stones (Aloisi, 2008). If we consider that nan(n)obacteria could be EPS accumulative and knowing that EPS contain DNA (Whitchurch et al., 2002; Steinberg and Holden, 2005), it is unlikely that this hypothesis fits with nanobes observed by Uwins et al. (1998), where no other microorganisms were detected.

Summary

Nan(n)obacteria emerged as a new form of life during the last two decades, based mainly on their capability to trigger infectious diseases. Their interpretation as simple proteins in kidney stones has been recently ruled out, although similar nano-objects have been also observed in geological records. The controversy about their existence (too small to be biologically viable) is still ongoing today because no universal origin can be attributed to these nanoparticles. The EM imaging does not present

enough evidence alone, and molecular and physiological data are required in order to try to define their properties.

Definition

Mineral particles less than 0.1 μm are a vital component of geochemical cycling in the Earth surface systems. Particles in this size range are generally termed “nanoparticles”; nanocrystals are nanoparticles that exhibit long-range structural order. Their small size implies that they may be relatively mobile in natural systems, as well as more chemically labile than large crystals. They have recently come to the forefront of material science, with new evidence that the properties of some materials are a strong function of particle size, particularly at the nanometer scale.

Nanocrystals are characterized by higher surface strain and disorder, higher surface reactivity, and differences in reaction kinetics compared to larger crystals of the same composition. These properties make them important reactive agents in natural systems, especially given that minerals in surface and near-surface environments are typically smaller and more highly disordered than minerals crystallized under ideal conditions. In general, the interest in biological nanomaterials is focused on specific properties that a given material can offer. For example, the electronic structure of nanocrystals is of particular interest from the perspective of material science. For a review of chemical and physical properties related to nanomineral structure and composition, see Gilbert and Banfield (2005).

The crystallization of biominerals spans eukaryotic (“true nucleus”) and prokaryotic organisms (Lowenstam and Weiner, 1989). Eukaryotes form geologically important structures that may be based on nanoparticles, such as the silica-reinforced shells of diatoms or the calcite shells of coccolithophores and foraminifera (Weiner and Dove, 2003). Prokaryotes dominate, however, among microorganisms that mediate the development of nanoparticles, in terms of their ubiquity in surface and subsurface environments and the compositional and structural range of materials they can form (Gilbert and Banfield, 2005). This article focuses mainly on bacterial nanoparticles that contain metals because of their importance in Earth surface and subsurface environments as well as their relevance to other disciplines related to nanoscience.

Bacterial nanocrystals

Induced versus controlled crystallization

The development of biominerals or biocrystals may be either biologically induced or biologically controlled by the bacteria (Lowenstam and Weiner, 1989). In *biologically controlled mineralization*, microbes exert genetic

and chemical control over the formation of precipitates that are designed to serve a particular function. In contrast, *biologically induced mineralization* yields particles that are secondary to a chemical process controlled by the microorganism. In this case, the precipitates serve no physiological purpose.

Biologically induced nanominerals can result from a range of bacterial processes, including respiration, detoxification, and ion uptake or expulsion during metabolism. Although minerals with a range of sizes and crystal structures can be produced as a result of biologically induced mineralization (e.g., Fortin et al., 2008), the nanometer-sized minerals are of particular interest because of their chemical reactivity as well as the potential for transport in natural systems. Reactivity is a consequence of the high proportion of surface atoms, which are chemically uncoordinated at the solution interface and less ordered than fully coordinated atoms in the structure.

Nanomineral formation can be induced in the extracellular environment, as a result of changes in solution chemistry caused by uptake or expulsion of ions (e.g., H^+) from the cell (Fortin et al., 2008). In addition, bacterial surfaces carry negative and positive charges due to the dissociation of functional groups integral to the cell wall (Beveridge, 1989). Sorption of ions to charged bacterial surfaces or sheaths can lower the nucleation energy for crystal formation and induce thick mantles to develop based on nanoparticles. This process can be observed during the growth of silica sheaths around bacteria and cyanobacteria, which may also incorporate metal ions (Ferris et al., 1986; Konhauser et al., 2004). More examples of induced mineralization are discussed below.

Extracellular nanominerals

Bacterial metal respiration is a process in which electrons are removed or accepted by a metal ion to generate energy for the cell. Specific bacteria are capable of either oxidation or reduction; for example, *Gallionella* spp. and *Leptothrix* spp. are known iron oxidizers, whereas *Shewanella* and *Geobacter* are genera associated with metal reduction. Metal oxidation and reduction (“redox”) by bacteria may take place in chemically stratified zones within a sediment or water column, or may occur in microscale zones (Nealson and Stahl, 1997; Sobolov and Roden, 2002). Minerals form when a change in metal valence induced by respiration affects the solubility of a metal, in the presence of a suitable counterion to react with the reduced or oxidized metal species; the minerals form by an induced process rather than a controlled one.

Iron- and manganese-oxidizing bacteria can produce copious quantities of nanoparticulate minerals via a respiratory process that strips electrons from lower valence states of the metal and transfers them to the electron transport chain (Tebo et al., 1997; Kappler and Straub, 2005). In the case of iron, particles of poorly crystalline ferric hydroxide result that are typically 3–5 nm in diameter;

these aggregate strongly and eventually form larger particles of more crystalline iron oxides (Kappler and Straub, 2005).

For metal-reducing bacteria, metals serve as the terminal electron acceptor during respiration rather than being assimilated by the bacteria. Metals transformed by bacteria during dissimilatory respiration that form nanoparticles include Fe, Mn, U, Tc, Cr, V, and Pu (Lloyd et al., 2002; Boukhalfa et al., 2007; Fortin et al., 2008). Of respirable metals, iron is ubiquitous and relatively abundant in most environments, and copious amounts of secondary ferrous or mixed valence precipitates may form. Reduction of Fe(III) by dissimilatory metal reducing bacteria such as *Shewanella putrefaciens* and *Geobacter metallireducens* can result in extracellular crystals of magnetite (Fe_3O_4) around 10 nm in diameter, which serve no known purpose for the organisms that produce them (Frankel and Bazylinski, 2003), in addition to larger crystals of minerals with different structures and compositions (Fortin et al., 2008).

Nanominerals associated with the bacterial cell wall

Soluble metals, such as species formed by V^{5+} and U^{6+} , can penetrate the outer membrane of Gram-negative bacteria and form nanometer-size precipitates via an induced process in the periplasm upon reduction during respiration, in addition to forming abundant extracellular precipitates (Figure 1) (Suzuki et al., 2002; Lloyd et al., 2002). Soluble cytochromes in the periplasm catalyze the reduction of the metals to lower valence, insoluble species, e.g., U(IV) and V(IV). These precipitates are several nanometers in diameter and may have considerable consequences for metal mobility in the environment (Suzuki et al., 2002). Recent evidence suggests, however, that extracellular proteins in biofilms inhibit the mobilization of nanoprecipitates by inducing aggregation (Moreau et al., 2007). Nanoparticles generally have a strong tendency to aggregate.

Nanocrystals, Microbially Induced, Figure 1 Precipitates containing V(IV) (a) or U(VI) (b) in *Shewanella putrefaciens* or *Geobacter sulfurreducens*, respectively, formed in the periplasmic space during the dissimilatory reduction of V^{5+} or U^{6+} . Transmission electron micrographs were obtained on thin sections prepared using conventional embedding techniques. Scale bar = 200 nm.

Intracellular nanominerals

Nanocrystalline precipitates of respired metals generally remain external to the cytoplasm or within the periplasm. It has been observed, however, that reduced iron is reoxidized and compartmentalized within the cytoplasm as clusters of 40–50 nm precipitates at the poles of *S. putrefaciens* CN32 during the dissimilatory reduction of iron (Figure 2) (Glasauer et al., 2002; Glasauer et al., 2007). The particles contain both ferric and ferrous iron, display a low degree of crystal order, and appear to be surrounded by a membrane. The function of the particles, if any, is still unknown.

Some soluble, oxidized forms of metals more scarce than Fe can penetrate the plasma membrane and precipitate as induced nanocrystals in the cytoplasm of bacteria, as well as form extracellular precipitates. Examples of these include gold, silver, tellurium, and cadmium; all are highly toxic, and chemical reduction may be part of a detoxification strategy (Southam and Beveridge, 1994; Klaus-Joerger et al., 2001; Baesman et al., 2007). In the case of gold and silver, the intracellular precipitates are highly crystalline and have distinctive morphologies (Southam and Beveridge, 1994; Klaus-Joerger et al., 2001). During detoxification of cadmium present in the extracellular environment, *Schizosaccharomyces pombe* produces intracellular nanocrystalline particles of cadmium sulfide, around 1.8 nm in size, which can act as quantum semiconductor crystallites (Klaus-Joerger et al., 2001).

The challenge in harnessing bacterial metabolism to produce nanoscale minerals lies in controlling the size

Nanocrystals, Microbially Induced, Figure 2 Transmission electron micrograph (TEM) showing intracellular Fe-particles at one end of a *Shewanella putrefaciens* CN32 cell, and ferric hydroxide sorbed to the cell exterior. *S. putrefaciens* produces the intracellular particles during dissimilatory reduction of the ferric hydroxide. Scale bar = 200 nm.

and crystal structure of the products. Extracellular precipitates are subject to the diverse range of chemical conditions that the cell encounters, resulting in amorphous or poorly crystalline materials with a high proportion of impurities (Gilbert and Banfield, 2005). In contrast, *biologically controlled mineralization* takes place in the tightly regulated intracellular environment and results in nanoscale minerals with architectures that are exquisitely defined (Bazylinski and Frankel, 2003). The only known example of bacteria that direct the formation of iron nanocrystals are the magnetotactic bacteria. The intracellular minerals they form consist of either magnetite or greigite (Fe_3S_4). Each crystal functions as a single domain magnet, termed a magnetosome. The magnetosomes are aligned in single or multiple chains within the cytoplasm (Figure 3), which increases the magnetic susceptibility. The function of the magnetosomes is unknown, although it has been widely speculated that the crystals help maintain the bacteria in their optimal environment within the freshwater or brackish aquatic systems where they are found (Bazylinski and Frankel, 2003). Magnetosome magnetite is of great interest because of its magnetic properties and crystal structures, and it is anticipated that understanding the molecular genetics of magnetosome formation will lead to the abiotic synthesis of nanocrystalline magnetite particles with the same morphologies and properties, as well as help explaining their occurrence (Bazylinski and Frankel, 2003).

Nanocrystals, Microbially Induced, Figure 3 Thin section of ARB-1, an uncultured magnetotactic bacterium, imaged by TEM. Magnetosomes are aligned in a short chain at the right of the cell. Large spheroid shapes within the cell are phosphorous-rich inclusions (Cox et al., 2002).

Future directions in microbial nanocrystal research

The use of living or intact bacteria to fabricate nanocrystals requires the cultivation of biomass on a large scale and selective extraction of the mineral particles that form, both of which present challenges. The greatest potential in harnessing bacterial activities for nanocrystal fabrication lies in identifying the genetic systems that control precipitation. The identified systems may then be applied using organisms that are more readily cultivated or to produce larger quantities of nanocrystals. Genetic engineering techniques may be used to exert greater control over the composition and crystal structures of the mineral products. An interesting new research direction in biomaterials considers the impact of biopolymers such as peptides and RNA on nanocrystal formation (Feldheim and Eaton, 2007). Future research may combine bacterial processes that produce abundant nanoparticles with exposure to biopolymers that mediate their formation to generate crystals that have been engineered to impart specific properties.

Summary

Bacterial nanocrystals are of great interest because of their importance in natural environments as well as their practical applications. Their broad relevance has joined scientists across disciplines from geology to biology and material science, which has rapidly advanced the understanding of nanoparticulate matter and its reactivity in natural settings. Controlled nanocrystal synthesis among bacteria is rare and yields relatively low amounts of solid relative to biomass. Induced crystallization processes can result in large volumes of poorly crystalline or morphologically heterogeneous minerals and span a wide range of elemental compositions. Harnessing biological reactions to control microbial nanocrystallization is an outstanding challenge and presents intriguing opportunities for new research paths. Finally, understanding the properties of nanocrystals as well as why some bacteria produce them is crucial to predicting how metals react and transform in natural environments.

Definition

Nickel, atomic number 28, is a member of the same group in the periodic table as iron, cobalt, and copper. In biology, nickel is a major trace element and part of the catalytic centers of many important metabolic enzymes.

Nickel is one of the most important trace metals in biology. While its concentration in most rocks is only between 10 and 150 $\mu\text{g g}^{-1}$, it is highly enriched in ultramafic rocks, like peridotite and serpentine (Sigel et al., 2006). Nickel is a key component in the active center of a number of enzymes involved in different microbial pathways (Ragsdale, 2007; Ermler et al., 1998). Three nickel metalloenzymes play important roles in the carbon cycle: CO dehydrogenase (CODH), acetyl-CoA synthase (ACS), and methyl-coenzyme M reductase (MCR). The first two enzymes are involved in carbon fixation of anaerobic microorganisms via the Wood–Ljungdahl or reductive acetyl-CoA pathway. CODH allows microorganisms to use carbon monoxide as sole carbon and energy source. It has been suggested that carbon monoxide can be consumed and produced in a bioenergetic cycle

Definition

Nickel, atomic number 28, is a member of the same group in the periodic table as iron, cobalt, and copper. In biology, nickel is a major trace element and part of the catalytic centers of many important metabolic enzymes.

Nickel is one of the most important trace metals in biology. While its concentration in most rocks is only between 10 and 150 $\mu\text{g g}^{-1}$, it is highly enriched in ultramafic rocks, like peridotite and serpentine (Sigel et al., 2006). Nickel is a key component in the active center of a number of enzymes involved in different microbial pathways (Ragsdale, 2007; Ermler et al., 1998). Three nickel metalloenzymes play important roles in the carbon cycle: CO dehydrogenase (CODH), acetyl-CoA synthase (ACS), and methyl-coenzyme M reductase (MCR). The first two enzymes are involved in carbon fixation of anaerobic microorganisms via the Wood–Ljungdahl or reductive acetyl-CoA pathway. CODH allows microorganisms to use carbon monoxide as sole carbon and energy source. It has been suggested that carbon monoxide can be consumed and produced in a bioenergetic cycle

(Dobbek et al., 2001; Voordouw, 2002). The Ni-containing CODH is involved in many reactions in anaerobic microorganisms: it catalyzes the oxidation of CO with H₂O to CO₂ and H₂ in carboxydophilic bacteria, and assists the oxidation of acetate to CO₂ in sulfate-reducing bacteria and archaea and the disproportionation of acetate to CH₄ and CO₂ in methanogenic archaea. In many groups of anaerobic microorganisms utilizing the reductive acetyl-CoA pathway, such as acetogenic bacteria or methanogenic archaea, CODH is often found in a complex with ACS (Strauss and Fuchs, 1993; Holo and Sirevag, 1986; Drennan et al., 2004). ACS catalyzes the formation of acetyl-CoA from CO, leading in combination with the CODH to the synthesis of acetate from two CO₂. These two enzymes play an important role in the global carbon cycle, since up to 10% of the organic carbon produced by photosynthesis is remineralized by anaerobic microorganisms involving CODH/ACS (Drake, 1994). MCR is the key enzyme of methanogenic archaea catalyzing the final step during the reduction of carbon dioxide to methane (Thauer, 1998). All biologically formed methane is produced by methanogenic organisms in the terminal step of anaerobic degradation. The nickel is located in a tetrapyrrole coenzyme named F₄₃₀, which is unique to methanogenic archaea. MCR catalyzes the reduction of methyl-coenzyme M with a reduced coenzyme B, leading to the release of methane and a heterodisulfide of the two coenzymes. The latter can be cleaved in an energy yielding reaction. Furthermore, in a process called “reverse methanogenesis,” methane is anaerobically oxidized with sulfate as electron acceptor. This process – known as AOM – is carried out by an uncultured group of archaea (ANME), which has been shown to contain high amounts of a modified MCR (Krüger et al., 2003; Hallam et al., 2003). Hydrogenases are a family of oxidoreductase enzymes that catalyze the reversible oxidation of molecular hydrogen. Nickel-containing hydrogenases have been isolated from bacteria and archaea (Voordouw, 1992). Finally, nickel is also present in a number of other enzymes, such as urease, a superoxide dismutase, and glyoxylases. The functions and biological roles of these metalloproteins have been described in detail (Sigel et al., 2006).

Recently, due to its strong involvement in geologically important microbial reactions, especially methanogenesis, AOM, and carbon fixation, nickel has raised interest as a potential biosignature for these processes and the involved microorganisms in recent or ancient environments (Reitner et al., 2005; Hausrath et al., 2007).

NITRIFICATION

Nitrification is the two-step microbial process by which ammonia (NH₃) is first oxidized to nitrite (NO₂[−]) which is, in a second reaction, converted to nitrate (NO₃[−]). See entry “[Nitrogen](#)” for detailed reading.

N

NAN(N)OBACTERIA

Muriel Pacton¹, Georges E. Gorin²

¹ETH Zurich, Zurich, Switzerland

²University of Geneva, Geneva, Switzerland

Synonyms

Living nanovesicles; Nanobes; Nanocalcifying particles (NCP); Nanoforms; Nanoglobules; Nanons; Nano-organisms; Nanoparticles

Biologists used the word *nanobacteria* to describe organisms that possibly enhance biomineralization such as that of kidney stones in humans, whereas *nannobacteria* is used by geologists for organisms responsible for mineral precipitation in terrestrial and extraterrestrial rocks.

Definition

Nan(n)obacteria are tiny globular objects, ranging in diameter from 20 to 200 nm, with the ability to nucleate minerals. They are the smallest known, self-replicating particles with slow growth rate. Because they are by definition down to 1/10 the size of bacteria, it raises the problem of whether or not an organism of this size is large enough to house necessary cell components such as DNA, RNA, and plasmids.

Introduction

The term “nan(n)obacteria” has been originally proposed by Folk (1993) to describe 20–200 nm wide nanovesicles observed in carbonates using scanning electron microscopy (SEM). Kajander and Çiftçioglu (1998) defined the role of similar tiny particles in kidney stone formation. Based on their mineralogical properties, nan(n)obacteria have also been called calcifying nanoparticles (CNP) by

these authors. Nan(n)obacteria-like particles have been observed in Martian meteorites, thereby raising questions about a primitive form of life (Bradley et al., 1997). CNP are studied extensively in pathogenic diseases as infectious agents by nucleating crystals (hydroxyapatite). Therefore, some comparisons have tentatively been made with the geological record. Although they display some evidences of bacterial nature, their living status is subject to controversy because of their small size and the fact that DNA extraction remains unsuccessful. On one hand, biologists discuss their metabolic existence and on the other hand geologists argue for widespread organic fossilization in palaeoenvironments. When interrelations between geology and microbiology are possible, they are looked at only from the point of view of experimental procedures (e.g., one emphasizes the use of DNA probes in geological samples). This prohibits an objective comparison of these very small particles.

Reported nan(n)obacteria in the literature

In the geological record, nan(n)obacteria-like particles are encountered mainly in carbonates: in calcite (Dix et al., 1999; Chen et al., 2005; Mamet and Pr  at, 2006), microbialites (Camoin et al., 1999), dolomite (Figure 1; Vasconcelos et al., 1995; Gournay et al., 1999; Wright, 1999; Al  i  ek, 2009), hydrothermal springs (Casanova et al., 1999), and oncolite laminations (Cavalazzi et al., 2007). They have also been observed in sandstones without mineral precipitation (Uwins et al., 1998) and on quartz overgrowth in crude oil (Spark et al., 2000).

In medical biology, CNP have been the focus of numerous studies on various pathogenic diseases (see Urbano and Urbano (2007) for a review), for example, gallbladder (Wang et al., 2006), nasopharyngeal cancer (Zhou et al., 2006), and renal stone formations (e.g., Kajander and   ift  i  glu (1998) and Jones et al. (2009)).

Nan(n)obacteria, Figure 1 Nan(n)obacteria encrusted by nanocrystals of carbonate on a quartz substrate. (Picture courtesy of Crisogono Vasconcelos.)

Characterization of purported nan(n)obacteria

Nan(n)obacteria exhibit some characteristics, which seem to correspond to the classical criteria indicating a biological origin: (1) a typical bacterial appearance (Kajander and Çiftçioglu, 1998; Uwins et al., 1998); (2) a slow growth in liquid cell culture media; (3) an expression of specific antigens (Hjelle et al., 2000; Miller et al., 2004) by using monoclonal antibodies commercially available through Nanobac Oy (Finland) as 8D10 and through Santa Cruz Biotechnology, USA, named GM-CSFR α ; (4) a staining with nucleic fluorochroms (Uwins et al., 1998; Miller et al., 2004) using 4',6-diamidino-2-phenylindole (DAPI), acridine orange, Hoechst 33258, Feulgen, and/or Picogreen; (5) a resistance to antibiotics such as tetracycline and citrate (Maniscalco and Taylor, 2004); (6) a sensitivity to calcium-chelating agents (Rawal and Pretorius, 2005); and (7) a DNA sequencing tentatively assigned to the α -2 subgroup of proteobacteria, which also includes *Brucella* and *Bartonella* species occurring within and outside of host cells (Kajander and Çiftçioglu, 1998; Çiftçioglu and Kajander, 1998). According to Cisar et al. (2000), they could come from PCR contaminant.

Possible origins for nan(n)obacteria

Due to the very small size of purported nan(n)obacteria, the hypothesis that they might represent living entities is very controversial. Several, alternative origins have been proposed:

Inorganic origin: Inorganic precipitates (Vecht and Ireland, 2000; Cisar et al., 2000) and artifacts due to sample preparation (e.g., coating for SEM, acid treatment, polishing artifacts) have been considered as an alternative origin for these nanostructures. However, nanostructures

Nan(n)obacteria, Figure 2 Chain of dolomite nanoglobules formed in *Halomonas meridiana* culture. (Picture courtesy of Monica Sanchez-Roman.)

can also be observed in samples that have not been exposed to these techniques (Folk and Lynch, 1997).

Extracellular polymeric substances (EPS): Reitner et al. (1995) have proposed that nanospheres were an initial calcification of EPS. They have been interpreted as early stages of dolomite precipitation in anaerobic cultures (Bontognali et al., 2008) and aerobic cultures (Figure 2; Sanchez-Roman et al., 2008). Similar observations have been made on aragonite nanocrystals that contained organic molecules (Benzerara et al., 2006).

Proteins: Tissue degradation caused by microbial activity can create nanobacteria-like particles of proteinous origin (Schieber and Arnott, 2003). In the case of kidney stones, it has been confirmed that nan(n)obacteria are in fact related to blood proteins (Martel and Young 2008), that is, fetuin (Raoult et al., 2008).

Small bacteria: Dwarf bacteria generally show a decrease in cell size. This is assumed to be the case of bacteria exposed to low nutrient or starvation conditions (Velimirov, 2001). Ultramicrobacteria exhibit a very low growth rate (Torella and Morita, 1981). The distinction between ultramicrobacteria and starvation forms is based on their physiological properties (Velimirov, 2001).

Viruses: Stressed bacteria overproduce vesicles that are apparently used to selectively eliminate unwanted material, for example, unfolded proteins (Soler et al., 2008). All fluorescent small-size particles are assumed to correspond to a DNA virus (Soler et al., 2008). Membrane vesicles seem to be produced by most bacteria and have been

detected in natural environments, including biofilms (Schooling and Beveridge, 2006).

Minimal conditions for a living cell

Theoretical calculations have been made in order to define the smallest size needed for a cell to have metabolic processes and accommodate the smallest genome. According to these assumptions, the minimal cell size should fall within the range of 100 nm (Boal, 1999), 140 nm (Maniloff et al., 1997), and 170 nm (Adams, 1999). Assuming a cell genome housing 250 genes (which is considered the minimal number needed to support heterotrophic cell growth in a nutrient-rich environment with a minimal metabolic pathway), a minimum diameter of 50 nm has been established, which could contain eight genes (Adams, 1999). Nevertheless, a cell with a size of only 50 nm, a 5 nm cell wall, 2 ribosomes, 520 protein molecules, and a DNA strand containing 8 genes is considered too small to function like recent bacteria, based on the smallest known living organism, that is, *Nanoarchaeum equitans* (Huber et al., 2002).

Universal origin for nan(n)obacteria?

The analogy between nan(n)obacteria-like particles in pathogenic diseases and geological records is often made even though the methodology differs. Nan(n)obacteria have not been found in any clinical condition that does not involve calcification, which is not the case of some geological samples (Uwins et al., 1998; Schieber and Arnott, 2003). Recently, nan(n)obacteria-like particles associated with kidney stone formation have been assigned directly to blood proteins reacting with antibodies that were so far claimed to be specifically associated to nan(n)obacteria (Martel and Young, 2008; Raoult et al., 2008). The latter authors suggested that they are nucleic-acid free. An alternative origin has been proposed where nan(n)obacteria could be the by-product of the living activities of bona fide bacteria inhabiting kidney stones (Aloisi, 2008). If we consider that nan(n)obacteria could be EPS accumulative and knowing that EPS contain DNA (Whitchurch et al., 2002; Steinberg and Holden, 2005), it is unlikely that this hypothesis fits with nanobes observed by Uwins et al. (1998), where no other microorganisms were detected.

Summary

Nan(n)obacteria emerged as a new form of life during the last two decades, based mainly on their capability to trigger infectious diseases. Their interpretation as simple proteins in kidney stones has been recently ruled out, although similar nano-objects have been also observed in geological records. The controversy about their existence (too small to be biologically viable) is still ongoing today because no universal origin can be attributed to these nanoparticles. The EM imaging does not present

enough evidence alone, and molecular and physiological data are required in order to try to define their properties.

Definition

Mineral particles less than 0.1 μm are a vital component of geochemical cycling in the Earth surface systems. Particles in this size range are generally termed “nanoparticles”; nanocrystals are nanoparticles that exhibit long-range structural order. Their small size implies that they may be relatively mobile in natural systems, as well as more chemically labile than large crystals. They have recently come to the forefront of material science, with new evidence that the properties of some materials are a strong function of particle size, particularly at the nanometer scale.

Nanocrystals are characterized by higher surface strain and disorder, higher surface reactivity, and differences in reaction kinetics compared to larger crystals of the same composition. These properties make them important reactive agents in natural systems, especially given that minerals in surface and near-surface environments are typically smaller and more highly disordered than minerals crystallized under ideal conditions. In general, the interest in biological nanomaterials is focused on specific properties that a given material can offer. For example, the electronic structure of nanocrystals is of particular interest from the perspective of material science. For a review of chemical and physical properties related to nanomineral structure and composition, see Gilbert and Banfield (2005).

The crystallization of biominerals spans eukaryotic (“true nucleus”) and prokaryotic organisms (Lowenstam and Weiner, 1989). Eukaryotes form geologically important structures that may be based on nanoparticles, such as the silica-reinforced shells of diatoms or the calcite shells of coccolithophores and foraminifera (Weiner and Dove, 2003). Prokaryotes dominate, however, among microorganisms that mediate the development of nanoparticles, in terms of their ubiquity in surface and subsurface environments and the compositional and structural range of materials they can form (Gilbert and Banfield, 2005). This article focuses mainly on bacterial nanoparticles that contain metals because of their importance in Earth surface and subsurface environments as well as their relevance to other disciplines related to nanoscience.

Bacterial nanocrystals

Induced versus controlled crystallization

The development of biominerals or biocrystals may be either biologically induced or biologically controlled by the bacteria (Lowenstam and Weiner, 1989). In *biologically controlled mineralization*, microbes exert genetic

and chemical control over the formation of precipitates that are designed to serve a particular function. In contrast, *biologically induced mineralization* yields particles that are secondary to a chemical process controlled by the microorganism. In this case, the precipitates serve no physiological purpose.

Biologically induced nanominerals can result from a range of bacterial processes, including respiration, detoxification, and ion uptake or expulsion during metabolism. Although minerals with a range of sizes and crystal structures can be produced as a result of biologically induced mineralization (e.g., Fortin et al., 2008), the nanometer-sized minerals are of particular interest because of their chemical reactivity as well as the potential for transport in natural systems. Reactivity is a consequence of the high proportion of surface atoms, which are chemically uncoordinated at the solution interface and less ordered than fully coordinated atoms in the structure.

Nanomineral formation can be induced in the extracellular environment, as a result of changes in solution chemistry caused by uptake or expulsion of ions (e.g., H^+) from the cell (Fortin et al., 2008). In addition, bacterial surfaces carry negative and positive charges due to the dissociation of functional groups integral to the cell wall (Beveridge, 1989). Sorption of ions to charged bacterial surfaces or sheaths can lower the nucleation energy for crystal formation and induce thick mantles to develop based on nanoparticles. This process can be observed during the growth of silica sheaths around bacteria and cyanobacteria, which may also incorporate metal ions (Ferris et al., 1986; Konhauser et al., 2004). More examples of induced mineralization are discussed below.

Extracellular nanominerals

Bacterial metal respiration is a process in which electrons are removed or accepted by a metal ion to generate energy for the cell. Specific bacteria are capable of either oxidation or reduction; for example, *Gallionella* spp. and *Leptothrix* spp. are known iron oxidizers, whereas *Shewanella* and *Geobacter* are genera associated with metal reduction. Metal oxidation and reduction (“redox”) by bacteria may take place in chemically stratified zones within a sediment or water column, or may occur in microscale zones (Nealson and Stahl, 1997; Sobolov and Roden, 2002). Minerals form when a change in metal valence induced by respiration affects the solubility of a metal, in the presence of a suitable counterion to react with the reduced or oxidized metal species; the minerals form by an induced process rather than a controlled one.

Iron- and manganese-oxidizing bacteria can produce copious quantities of nanoparticulate minerals via a respiratory process that strips electrons from lower valence states of the metal and transfers them to the electron transport chain (Tebo et al., 1997; Kappler and Straub, 2005). In the case of iron, particles of poorly crystalline ferric hydroxide result that are typically 3–5 nm in diameter;

these aggregate strongly and eventually form larger particles of more crystalline iron oxides (Kappler and Straub, 2005).

For metal-reducing bacteria, metals serve as the terminal electron acceptor during respiration rather than being assimilated by the bacteria. Metals transformed by bacteria during dissimilatory respiration that form nanoparticles include Fe, Mn, U, Tc, Cr, V, and Pu (Lloyd et al., 2002; Boukhalfa et al., 2007; Fortin et al., 2008). Of respirable metals, iron is ubiquitous and relatively abundant in most environments, and copious amounts of secondary ferrous or mixed valence precipitates may form. Reduction of Fe(III) by dissimilatory metal reducing bacteria such as *Shewanella putrefaciens* and *Geobacter metallireducens* can result in extracellular crystals of magnetite (Fe_3O_4) around 10 nm in diameter, which serve no known purpose for the organisms that produce them (Frankel and Bazylinski, 2003), in addition to larger crystals of minerals with different structures and compositions (Fortin et al., 2008).

Nanominerals associated with the bacterial cell wall

Soluble metals, such as species formed by V^{5+} and U^{6+} , can penetrate the outer membrane of Gram-negative bacteria and form nanometer-size precipitates via an induced process in the periplasm upon reduction during respiration, in addition to forming abundant extracellular precipitates (Figure 1) (Suzuki et al., 2002; Lloyd et al., 2002). Soluble cytochromes in the periplasm catalyze the reduction of the metals to lower valence, insoluble species, e.g., U(IV) and V(IV). These precipitates are several nanometers in diameter and may have considerable consequences for metal mobility in the environment (Suzuki et al., 2002). Recent evidence suggests, however, that extracellular proteins in biofilms inhibit the mobilization of nanoprecipitates by inducing aggregation (Moreau et al., 2007). Nanoparticles generally have a strong tendency to aggregate.

Nanocrystals, Microbially Induced, Figure 1 Precipitates containing V(IV) (a) or U(VI) (b) in *Shewanella putrefaciens* or *Geobacter sulfurreducens*, respectively, formed in the periplasmic space during the dissimilatory reduction of V^{5+} or U^{6+} . Transmission electron micrographs were obtained on thin sections prepared using conventional embedding techniques. Scale bar = 200 nm.

Intracellular nanominerals

Nanocrystalline precipitates of respired metals generally remain external to the cytoplasm or within the periplasm. It has been observed, however, that reduced iron is reoxidized and compartmentalized within the cytoplasm as clusters of 40–50 nm precipitates at the poles of *S. putrefaciens* CN32 during the dissimilatory reduction of iron (Figure 2) (Glasauer et al., 2002; Glasauer et al., 2007). The particles contain both ferric and ferrous iron, display a low degree of crystal order, and appear to be surrounded by a membrane. The function of the particles, if any, is still unknown.

Some soluble, oxidized forms of metals more scarce than Fe can penetrate the plasma membrane and precipitate as induced nanocrystals in the cytoplasm of bacteria, as well as form extracellular precipitates. Examples of these include gold, silver, tellurium, and cadmium; all are highly toxic, and chemical reduction may be part of a detoxification strategy (Southam and Beveridge, 1994; Klaus-Joerger et al., 2001; Baesman et al., 2007). In the case of gold and silver, the intracellular precipitates are highly crystalline and have distinctive morphologies (Southam and Beveridge, 1994; Klaus-Joerger et al., 2001). During detoxification of cadmium present in the extracellular environment, *Schizosaccharomyces pombe* produces intracellular nanocrystalline particles of cadmium sulfide, around 1.8 nm in size, which can act as quantum semiconductor crystallites (Klaus-Joerger et al., 2001).

The challenge in harnessing bacterial metabolism to produce nanoscale minerals lies in controlling the size

Nanocrystals, Microbially Induced, Figure 2 Transmission electron micrograph (TEM) showing intracellular Fe-particles at one end of a *Shewanella putrefaciens* CN32 cell, and ferric hydroxide sorbed to the cell exterior. *S. putrefaciens* produces the intracellular particles during dissimilatory reduction of the ferric hydroxide. Scale bar = 200 nm.

and crystal structure of the products. Extracellular precipitates are subject to the diverse range of chemical conditions that the cell encounters, resulting in amorphous or poorly crystalline materials with a high proportion of impurities (Gilbert and Banfield, 2005). In contrast, *biologically controlled mineralization* takes place in the tightly regulated intracellular environment and results in nanoscale minerals with architectures that are exquisitely defined (Bazylinski and Frankel, 2003). The only known example of bacteria that direct the formation of iron nanocrystals are the magnetotactic bacteria. The intracellular minerals they form consist of either magnetite or greigite (Fe_3S_4). Each crystal functions as a single domain magnet, termed a magnetosome. The magnetosomes are aligned in single or multiple chains within the cytoplasm (Figure 3), which increases the magnetic susceptibility. The function of the magnetosomes is unknown, although it has been widely speculated that the crystals help maintain the bacteria in their optimal environment within the freshwater or brackish aquatic systems where they are found (Bazylinski and Frankel, 2003). Magnetosome magnetite is of great interest because of its magnetic properties and crystal structures, and it is anticipated that understanding the molecular genetics of magnetosome formation will lead to the abiotic synthesis of nanocrystalline magnetite particles with the same morphologies and properties, as well as help explaining their occurrence (Bazylinski and Frankel, 2003).

Nanocrystals, Microbially Induced, Figure 3 Thin section of ARB-1, an uncultured magnetotactic bacterium, imaged by TEM. Magnetosomes are aligned in a short chain at the right of the cell. Large spheroid shapes within the cell are phosphorous-rich inclusions (Cox et al., 2002).

Future directions in microbial nanocrystal research

The use of living or intact bacteria to fabricate nanocrystals requires the cultivation of biomass on a large scale and selective extraction of the mineral particles that form, both of which present challenges. The greatest potential in harnessing bacterial activities for nanocrystal fabrication lies in identifying the genetic systems that control precipitation. The identified systems may then be applied using organisms that are more readily cultivated or to produce larger quantities of nanocrystals. Genetic engineering techniques may be used to exert greater control over the composition and crystal structures of the mineral products. An interesting new research direction in biomaterials considers the impact of biopolymers such as peptides and RNA on nanocrystal formation (Feldheim and Eaton, 2007). Future research may combine bacterial processes that produce abundant nanoparticles with exposure to biopolymers that mediate their formation to generate crystals that have been engineered to impart specific properties.

Summary

Bacterial nanocrystals are of great interest because of their importance in natural environments as well as their practical applications. Their broad relevance has joined scientists across disciplines from geology to biology and material science, which has rapidly advanced the understanding of nanoparticulate matter and its reactivity in natural settings. Controlled nanocrystal synthesis among bacteria is rare and yields relatively low amounts of solid relative to biomass. Induced crystallization processes can result in large volumes of poorly crystalline or morphologically heterogeneous minerals and span a wide range of elemental compositions. Harnessing biological reactions to control microbial nanocrystallization is an outstanding challenge and presents intriguing opportunities for new research paths. Finally, understanding the properties of nanocrystals as well as why some bacteria produce them is crucial to predicting how metals react and transform in natural environments.

NICKEL, BIOLOGY

Martin Krüger
 Federal Institute for Geosciences and Natural Resources,
 Hannover, Germany

Definition

Nickel, atomic number 28, is a member of the same group in the periodic table as iron, cobalt, and copper. In biology, nickel is a major trace element and part of the catalytic centers of many important metabolic enzymes.

Nickel is one of the most important trace metals in biology. While its concentration in most rocks is only between 10 and 150 $\mu\text{g g}^{-1}$, it is highly enriched in ultramafic rocks, like peridotite and serpentine (Sigel et al., 2006). Nickel is a key component in the active center of a number of enzymes involved in different microbial pathways (Ragsdale, 2007; Ermler et al., 1998). Three nickel metalloenzymes play important roles in the carbon cycle: CO dehydrogenase (CODH), acetyl-CoA synthase (ACS), and methyl-coenzyme M reductase (MCR). The first two enzymes are involved in carbon fixation of anaerobic microorganisms via the Wood–Ljungdahl or reductive acetyl-CoA pathway. CODH allows microorganisms to use carbon monoxide as sole carbon and energy source. It has been suggested that carbon monoxide can be consumed and produced in a bioenergetic cycle

(Dobbek et al., 2001; Voordouw, 2002). The Ni-containing CODH is involved in many reactions in anaerobic microorganisms: it catalyzes the oxidation of CO with H₂O to CO₂ and H₂ in carboxydophilic bacteria, and assists the oxidation of acetate to CO₂ in sulfate-reducing bacteria and archaea and the disproportionation of acetate to CH₄ and CO₂ in methanogenic archaea. In many groups of anaerobic microorganisms utilizing the reductive acetyl-CoA pathway, such as acetogenic bacteria or methanogenic archaea, CODH is often found in a complex with ACS (Strauss and Fuchs, 1993; Holo and Sirevag, 1986; Drennan et al., 2004). ACS catalyzes the formation of acetyl-CoA from CO, leading in combination with the CODH to the synthesis of acetate from two CO₂. These two enzymes play an important role in the global carbon cycle, since up to 10% of the organic carbon produced by photosynthesis is remineralized by anaerobic microorganisms involving CODH/ACS (Drake, 1994). MCR is the key enzyme of methanogenic archaea catalyzing the final step during the reduction of carbon dioxide to methane (Thauer, 1998). All biologically formed methane is produced by methanogenic organisms in the terminal step of anaerobic degradation. The nickel is located in a tetrapyrrole coenzyme named F₄₃₀, which is unique to methanogenic archaea. MCR catalyzes the reduction of methyl-coenzyme M with a reduced coenzyme B, leading to the release of methane and a heterodisulfide of the two coenzymes. The latter can be cleaved in an energy yielding reaction. Furthermore, in a process called “reverse methanogenesis,” methane is anaerobically oxidized with sulfate as electron acceptor. This process – known as AOM – is carried out by an uncultured group of archaea (ANME), which has been shown to contain high amounts of a modified MCR (Krüger et al., 2003; Hallam et al., 2003). Hydrogenases are a family of oxidoreductase enzymes that catalyze the reversible oxidation of molecular hydrogen. Nickel-containing hydrogenases have been isolated from bacteria and archaea (Voordouw, 1992). Finally, nickel is also present in a number of other enzymes, such as urease, a superoxide dismutase, and glyoxylases. The functions and biological roles of these metalloproteins have been described in detail (Sigel et al., 2006).

Recently, due to its strong involvement in geologically important microbial reactions, especially methanogenesis, AOM, and carbon fixation, nickel has raised interest as a potential biosignature for these processes and the involved microorganisms in recent or ancient environments (Reitner et al., 2005; Hausrath et al., 2007).

NITRIFICATION

Nitrification is the two-step microbial process by which ammonia (NH₃) is first oxidized to nitrite (NO₂[−]) which is, in a second reaction, converted to nitrate (NO₃[−]). See entry “[Nitrogen](#)” for detailed reading.

NITROGEN

Volker Thiel
University of Göttingen, Göttingen, Germany

Definition

Nitrogen is a nonmetal element with atomic number 7 and atomic mass of 14.00674 u. It was discovered in 1772 by Daniel Rutherford (1749–1819), a Scottish physician, botanist and chemist (Weeks, 1934).

Basic information

Nitrogen mainly occurs as dinitrogen (N₂), a diatomic, colorless, odorless, and inert gas at standard conditions. The atoms of N₂ are connected via an extremely stable triple bond, the strongest in nature (bond energy = 945 kJ mol⁻¹). N₂ constitutes 78.1 vol% of the atmosphere, making up the largest nitrogen reservoir on earth, followed by sediments and the oceans. Other, geobiologically relevant forms of inorganic nitrogen in fresh and marine waters, soils, and sediments include ammonia (NH₃), its ionic form ammonium (NH₄⁺), nitrite (NO₂⁻), nitrate (NO₃⁻), and gaseous nitrogen oxides (N₂O, NO_x) (Bashkin, 2002). An overview about major global nitrogen reservoirs is given in Table 1.

Nitrogen is one of the “biological elements” (beside C, H, O, P, and S), and is a major component of amino acids/proteins, nucleic acids (DNA, RNA), phospholipids, porphyrins, and secondary metabolites. According to the “Redfield–Richards Ratio,” the C:N:P ratio of phytoplanktonic biomass is, with some variation, 106:16:1 (C/N = 6.6). The C/N ratio of terrestrial plants is substantially more variable and also tends to be larger than that for marine phytoplankton, mainly due to a higher portion of nitrogen-free cellulose- and lignin-based wooden tissues. Although biomass plays only a minor role as a global nitrogen reservoir

(Table 1), nitrogen is, after carbon and oxygen, quantitatively the most abundant element in living organisms and its biogeochemical cycle is of great importance in the biosphere. The key processes involved in the nitrogen cycle are the following. For a schematic overview, see Figure 1).

Biological nitrogen fixation

Biological nitrogen fixation refers to the biological conversion of dinitrogen (N₂) into ammonia (NH₃), ammonium (NH₄⁺), and various organic compounds, and is the ultimate source of nitrogen for all organisms. There are two major limitations for biological nitrogen fixation (Bashkin, 2002). First, because of the stability of the triple bond in N₂, nitrogen fixation requires a high energy input. Only some symbiotic and non-symbiotic bacteria, archaea, and algae, the so-called nitrogen fixers or diazotrophs, are able to perform the reduction of N₂, employing a specific Fe and Mo-bearing enzyme, nitrogenase, which catalyzes the following reaction:

Second, nitrogenase is rapidly, and irreversibly, deactivated by oxygen. Therefore, only those organisms that live in anoxic environments or that can locally create such an environment will fix nitrogen. In terrestrial habitats, symbiotic bacteria, of which the genus *Rhizobium* is the most well studied, are important nitrogen fixers. These bacteria are found on the roots of leguminous plants (peas, soybeans) and some woody shrubs and trees. In aquatic systems, including the oceans, cyanobacteria are considered as the most important players in nitrogen fixation (Stal and Zehr, 2008). In cyanobacteria, nitrogen fixation takes place in particular cell compartments, the heterocysts, which are well secluded from the sites of oxygen production (see entry *Cyanobacteria*). N₂ fixation in

Nitrogen, Table 1 Major global nitrogen reservoirs-(After Reeburgh, 1997; Purvaja et al., 2008.)

Reservoir	Tg N (1 Tg = 10 ¹² g)
Atmosphere	
N ₂	3.9 × 10 ⁹
Fixed N	1.3 × 10 ³
N ₂ O	1.3 × 10 ³
Ocean	
N ₂	2.2 × 10 ⁷
N ₂ O	1.7 × 10 ²
Inorganic N	6.0 × 10 ⁵
Organic N	2.0 × 10 ⁵
Biomass	
Marine (plants)	3.0 × 10 ²
Marine (animals)	1.7 × 10 ²
Terrestrial	3.5 × 10 ⁴
Soil	9.5 × 10 ⁴
Sediments	4.0 × 10 ⁷

Nitrogen, Figure 1 Major pathways in the biogeochemical nitrogen cycle. 1 = Biological nitrogen fixation, 2 = Ammonia assimilation, 3 = Nitrification, 4 = Assimilatory nitrate reduction, 5 = Ammonification, 6 = Denitrification (dissimilatory nitrate reduction), 7 = Anammox.

Archaea is exclusive of, but widespread within, methanogenic euryarchaeota (Cabello et al., 2004, see entry *Archaea*). In addition to the natural pathways, anthropogenic processes, namely fertilizer production and fossil fuel combustion, may fix N_2 , and greatly accelerate the global nitrogen cycle (Gruber and Galloway, 2008). In the 1990s, these sources of anthropogenic nitrogen to the environment amounted to more than 160 Tg N year⁻¹. On a global basis, this is more than that supplied by natural biological nitrogen fixation on land (110 Tg N year⁻¹) or in the ocean (140 Tg N year⁻¹) (Gruber and Galloway, 2008).

Ammonia assimilation

Ammonia assimilation (uptake) is the process by which NH_3/NH_4^+ is transferred to organic nitrogen-containing compounds (e.g., amino acids or nucleotides; Madigan and Martinko, 2006). Such direct assimilation of NH_3/NH_4^+ into biomass has significant energetic advantages for those organisms which are able to use this form of nitrogen. In oxic environments, however, ammonium ions have a very limited lifetime because they are easily consumed in the nitrification process (see below).

Nitrification

Nitrification is the process by which ammonium is oxidized to nitrite and further to nitrate. The process includes two conjugated stages both of which are performed by aerobic bacteria, mainly chemoautotrophs (Meiklejohn, 2006). At present, no organism able to perform both steps simultaneously is known. The first stage of nitrification is the oxidation of ammonium to nitrite, according to the following reaction:

Representative bacteria that oxidize ammonium to nitrite include *Nitrosomonas* (very common in soils), *Nitrospira*, and *Nitrocystis* species. Notably, it has recently been reported that some bacteria (*Thiocapsa* sp., *Rhodopseudomonas* sp.) oxidize nitrite to nitrate in the light, thus using nitrite as an electron donor for photosynthesis. So far, this is the only known photosynthetic oxidation in the nitrogen cycle (Schott et al., 2010).

The second step in nitrification is the oxidation of nitrite to nitrate.

Representative bacteria that oxidize nitrite to nitrate include *Nitrobacter* (very common in soils), *Nitrospina*, and *Nitrococcus* species.

Artificial fertilizers containing reduced forms of nitrogen, namely urea and ammonium sulfate ($(NH_4)_2SO_4$), may fuel the nitrification process in well-drained agricultural soils. This has considerable environmental consequences, because in the nitrification process, some

intermediates like hydroxylamine (NH_2OH), NO, and N_2O are produced in significant amounts. Particularly the release of N_2O to the atmosphere may cause considerable environmental problems with respect to ozone depletion and global warming effects (IPCC, 2007). Nitrate in the environment is subject to two major pathways, assimilatory nitrate reduction and denitrification (see below).

Assimilatory nitrate reduction

Assimilatory nitrate reduction is defined as the reduction of nitrate (NO_3^-) and assimilation (uptake) of the nitrate-derived nitrogen into biomass. This pathway is somewhat more energy-expensive than ammonia assimilation, and therefore, it is prevalent when reduced nitrogen, i.e., ammonium, is low in supply, such as in aerated soils or in the oxic water column of aquatic environments. Assimilatory nitrate reduction is a primary nitrogen input of many microorganisms. Plants can commonly assimilate both ammonium and nitrate.

Ammonification

Ammonification refers to the breakdown of organic nitrogen into ammonium (NH_4^+). Strictly speaking, it is a two-step process (Libes, 1992). In the initial stage, particular organic nitrogen (PON) compounds are broken down to smaller dissolved molecules, i.e., dissolved organic nitrogen (DON). The DON is then further processed by heterotrophic bacteria to form ammonium. This process is actually called “ammonification,” and involves the enzymatically driven hydrolysis of peptide bonds of proteins to form amino acids, and the subsequent cleavage of the amino groups from the molecules. The resulting ammonium can be assimilated or microbially oxidized in the nitrification process, as outlined above.

Denitrification

Denitrification is the biologically facilitated reduction of nitrate (NO_3^-) to N_2 and other gaseous intermediates, mostly N_2O , which may return to the atmosphere (Bashkin, 2002). In denitrification, heterotrophic bacteria, such as members of the genera *Bacillus*, *Paracoccus*, and *Pseudomonas* (Madigan and Martinko, 2006), and some archaea (Cabello et al., 2004) oxidize organic matter by using nitrate as their electron acceptor:

Recent work has also shown that nitrate reduction can be coupled to methane oxidation (Raghoebarsing et al., 2006). Furthermore, several reactions of nitrate with reduced inorganic species have been reported that may also lead to the reduction of nitrate, whether biologically facilitated (Fe(II); Muehe et al., 2009) or not (MnO, “chemodenitrification”; Brandes et al., 2007). Denitrification leads to an overall loss of organic nitrogen (Hulth et al., 2005). It is the most energetically favorable anaerobic respiration process, with an energy yield only slightly

less than that of aerobic (O_2) respiration. During denitrification, some of the nitrate is not assimilated into biomass but reduced sequentially involving the following reduction steps (canonical denitrification):

and the overall reaction

Denitrification is usually thought to prevail mainly in soils, waters, and sediments under suboxic or anoxic conditions (Libes, 1992), because O_2 acts as a competing electron acceptor for nitrate, and key enzymes of the denitrification pathways are inhibited by O_2 . However, it has recently been reported that denitrification is also proceeding in oxic marine sediments (Gao et al., 2010). Evidently, denitrification is not necessarily inhibited in the presence of substantial oxygen concentrations but rather the co-respiration of O_2 and nitrate occurs. It is as yet unknown, whether this co-metabolism takes place in a single organism, or in different populations within the microbial community.

Like in the nitrification process, denitrification produces gaseous intermediates that cause environmental problems with respect to ozone depletion and global warming effects (Bateman and Baggs, 2005). N_2O is the quantitatively most important of these intermediates. It becomes particularly abundant under acidic conditions of denitrification, and may account for 0–20% of the gaseous nitrogen released (N_2 : 80–100%; Bashkin, 2002). In agriculture, denitrification is an undesired process because it removes nitrate, a nitrogen source amenable for plants, from the soil, thus decreasing soil fertility.

Anammox

Anammox, the anaerobic oxidation of ammonium, has only recently been recognized as an important route in the marine nitrogen cycle (Ward, 2003; Dalsgaard et al., 2005). In oxygen-deficient systems, anammox bacteria remove ammonium by reacting it with nitrite (NO_2^-) to form N_2 :

The anammox bacteria are highly specialized and belong to the order Planctomycetales (Schmid et al., 2005). Anammox was recognized as a major sink for fixed inorganic nitrogen in coastal sediments, in anoxic waters of the Black Sea, and in oxygen minimum zones in upwelling systems (Kuyper et al., 2003, 2005). In isotope labeling studies on surface sediments, anammox was found to account for 4–79% of the total N_2 production (Engström et al., 2005). On a global scale, it was estimated that anammox is responsible for up to 50% of the removal of fixed nitrogen from the world's oceans (Ward, 2003; Dalsgaard et al., 2005).

Geological and evolutionary aspects

Being a major constituent of the precursor biomass, organic nitrogen is generally found in fossil organic matter, i.e., kerogen, coal, thermogenic natural gas, and crude oils. However, organic nitrogen tends to become more and more depleted over geological times, as a result of preferential loss of N-bearing functional groups from organic matter during burial (e.g., desamination).

Whereas nitrogen is abundant in the atmospheric and biological pools, nitrogen-containing rocks and minerals are relatively scarce. Nitrogen occurs naturally only in a few relatively rare minerals, of which the nitrate salts saltpeter (KNO_3) and Chile saltpeter ($NaNO_3$) are quantitatively most abundant. Due to the extremely high solubility, these salts are stable only in hyperarid (precipitation <5 mm/year) settings such as the Atacama Desert in Chile. Here, the Chile saltpeter ores, also known as “caliche,” are soil-hosted ($NaNO_3$ content 3% to >13%, reserves ca. 500,000,000 t). The sources and formation mechanisms of the Atacama nitrate ores have long been debated (Ericksen, 1983). Recent isotope studies support an abiotic origin (Böhlke et al., 1997; Michalski et al., 2004). According to these studies, the main source of the Chilean saltpeter deposits is the precipitation of nitrate produced by photochemical reactions in the atmosphere, and the long-term accumulation in the absence of leaching and biological activity. It has also been suggested that volcanic eruptions from the close-by 70,000 km² Altiplano-Puna volcanic plateau may have fueled the thermal and electric (lightning-induced) fixation of atmospheric nitrogen as nitrate.

Apart from the formation of the actual nitrogen minerals, the adsorption of ammonium and its exchange for alkali metals in clay minerals are important and ubiquitous processes that decrease the bioavailability of nitrogen in sediments and soils, with major consequences for nitrogen turnover rates and soil fertility (Rosenfeld, 1979; Mamo et al., 1993). Moreover, studies revealed evidence that exchange reactions between potassium and ammonium are the dominant control of N_2 generation at depth, and the storage, release, and migration of nitrogen gas in sedimentary rocks. As a consequence, nitrogen frequently occurs as an undesired component natural gas that may potentially reduce the quality of hydrocarbon gas reservoirs (Krooss et al., 2006; Mingram et al., 2005).

The modern biogeochemical cycle of nitrogen depends on two obligately aerobic steps related to nitrification, i.e., ammonium oxidation to nitrite, and nitrite oxidation to nitrate. Hence, closure of the nitrogen cycle, as it is proceeding today, could be achieved only when free oxygen became available after the “Great Oxidation Event” ca. 2.3 billion years ago and promoted the evolution of aerobic ammonia and nitrite oxidizers (see entry *Critical Intervals in Earth History*). It is unknown whether electron acceptors other than oxygen, such as Fe^{3+} , could have been used as electron acceptors fueling the nitrogen cycle prior to rise of oxygen (Bashkin, 2002).

Likewise, the different routes for nitrogen fixation and assimilation require a portfolio of specialized biochemical pathways operating under different environmental conditions. Because a number of metalloenzymes are necessary for nitrogen fixation and assimilation, it is likely that the availability of transition metals has been a major control on the evolution of nitrogen assimilation pathways over Earth history (Zerkle et al., 2006; Glass et al., 2009). As an example, Fe and Mo are essential elemental components of the nitrogen-fixing enzyme, nitrogenase, and in enzymes responsible for the assimilation of inorganic nitrogen. Whereas Fe is scarce in the well-oxygenated modern oceans, it was abundant in anoxic Archean surface and deep oceans. Similar changes must have occurred in the abundance of Mo but with an opposite sense of direction, because Mo is more soluble in oxygenated than in reducing waters (Zerkle et al., 2006; Anbar, 2008; Scott et al., 2008). It was therefore hypothesized that photosynthesis-derived O_2 in late Archean oceans, particularly the "Great Oxidation Event," mobilized Mo and enabled the evolution of Mo-based N_2 fixation and the Mo-dependent enzymes for assimilation and denitrification by prokaryotes (Glass et al., 2009).

Summary

Nitrogen is one of the "biological elements" that constitutes organic compounds and its biogeochemical cycle is of utmost importance in the biosphere. The nitrogen cycle is mainly driven by prokaryotes and involves different nitrogen species, mainly N_{org} , NH_4^+ , N_2 , N_2O , NO_2^- , and NO_3^- . Nitrogen mostly occurs as dinitrogen (N_2) in the atmosphere and, in a dissolved form, in aquatic systems. Reductive conversion of inert N_2 into biologically accessible forms (organic compounds, NH_4) is an energy expensive process that requires specific enzymes (nitrogenase), and is only accomplished by a number of specialized organisms (diazotrophs). Further reactions used either for assimilatory purposes or in respiratory pathways involve anaerobic redox processes (anammox $NH_4^+ + NO_2^- \rightarrow N_2$), anaerobic/aerobic reductions (denitrification, $NO_3^- \rightarrow N_2$), and aerobic oxidations (nitrification; $NH_4^+ \rightarrow NO_2^- \rightarrow NO_3^-$) of the various nitrogen species. It is unknown whether and how the aerobic steps closing the modern nitrogen cycle were substituted early in Earth history, i.e., before the rise of oxygen. In the geological realm, nitrogen rarely occurs in a few highly soluble minerals such as saltpeter (KNO_3 , $NaNO_3$). In addition, it is a constituent element of clay minerals (ammonium), sedimentary organic matter, including kerogen, coal, natural gas, and crude oil, but its reservoir sizes and the modes of occurrence and formation are as yet not well constrained.
